The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices.

Copyright © 1976 by the American Agricultural Economics Association.

An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except that concerning "Books Reviewed" and "Books Received," should be addressed to the editor, William G. Tomek, Department of Agricultural Economics, Cornell University, Ithaca, New York 14853.

Communications concerning books for review and books submitted for announcement in the *Journal* should be sent to the book review editor, Francis E. Walker, Department of Agricultural Economics and Rural Sociology, Ohio State University, Columbus, Ohio 43210.

A Simulation Model for Evaluating Worldwide Buffer Stocks of Wheat

Shlomo Reutlinger

Stochastic simulation is advocated for quantifying the impact of alternative buffer stock levels and storage policies on stabilizing world wheat supplies and for estimating the corresponding benefits and losses to the world economy, to the storage operation itself, to consumers, and to producers. Illustrative runs of the model show that stock levels which are optimal in terms of direct costs and benefits are likely to be too low to afford satisfactory levels of stabilization. However, buffer stock programs operated with insurance-oriented storage rules could provide satisfactory protection against extreme shortfalls in grain supplies at a reasonably low cost.

Key words: buffer stocks, grain storage, stabilization, stochastic simulation, wheat.

The debate over world food stocks—how much, the rules for accumulation and release, and who should pay—continues to remain high on the agenda of public debate. The economics profession has yet to make a substantial contribution on this important issue of public policy. On the one hand, applied welfare economics has given insights into who gains from stabilization and economists have constructed models to estimate optimum storage levels, where the optima are defined in terms of single narrow economic or financial objectives (see Gustafson; Hueth and Schmitz; Oi; Samuelson 1972; Waugh). On the other hand, some workers have made estimates of the storage levels needed to stabilize supplies without providing a meaningful analysis of costs and benefits (see USDA). Many studies analyze the effect of storage operations on the basis of a probability distribution of production without regard to the sequence of good and bad harvests or else project the storage effects on the basis of a particular past sequence of years (see USDA, UN). All estimates of the effects of storage on the world's food economy are based on aggregate production and consumption data and abstract from spatial and trade constraints.

If not much else, the current public debate over international grain storage levels and rules clearly illustrates that it would be futile to attempt to influence the course of decisions by analyzing any one single dimension of storage effects. There is clearly a distinct concern for maximizing expected benefits (or minimizing expected costs) as well as for increasing price and quantity stability. Equally, if not more importantly, any discussion of national or international storage operations must confront issues arising from the incidence of benefits or losses to consumers and producers (importing and exporting countries). In theory it is possible to resolve the trade-offs between diverse objectives by specifying an appropriate social welfare function. In practice such a specification is an elusive goal for it involves subjective judgments on which a priori agreement among the parties is unlikely to occur.

The approach taken in this study clearly departs from the pursuit of a single optimal solution. A model is used to trace out the implications of several levels of storage activity and storage rules for several objectives. In the interest of providing useful insights on the general orders of magnitude of the impact of storage activities, the model is purposely kept simple. Several shortcomings of the model in terms of the complexity of the decision environment of the real world will be discussed

---

Shlomo Reutlinger is a senior economist with the International Bank for Reconstruction and Development.

This paper is based on a larger research project by the author aimed at specifying country models for evaluating buffer stocks and also draws on a earlier paper by the author (1971). The author is grateful to David Blum for research assistance, to C. J. A. Jansen, and to the anonymous reviewers for their substantial contributions toward improving the clarity of exposition.

and presented as appropriate topics for subsequent research.

The Model

In attempting to estimate worldwide price and consumption fluctuations with and without storage, the world is viewed as one unified market. Fluctuations in world consumption and price are assumed to depend only on fluctuations in world production and the extent of storage activity, i.e., any friction arising from trade constraints or shipping costs which separate regions of production and consumption is disregarded. Much more sophisticated and time-consuming models and data are needed to estimate the effects of buffer stocks in a world of segregated markets.

The model simulates fluctuations in the consumption and price of wheat under various levels of storage and with various storage rules governing the accumulation and release of stocks. World grain production is estimated on the basis of a large random sample drawn from a known probability distribution. Price is determined on the basis of a demand function relating the world price to the quantity of grain available for consumption. In any given year, grain supplies depend on the level of production and the amount of grain put into or taken out of storage.

The level of storage activity is determined by the level of production and the storage rules and is constrained by storage capacity and the amount of grain stored in previous years. The storage rules are as follows. If production is above a prespecified level (and the price below a certain level), the surplus grain is put into storage. If production is below a prespecified level (and the price above a certain level), grain is withdrawn from storage to augment supplies from production up to the prespecified level. The actual amount stored or withdrawn from storage is determined by simulating sequences of annual production levels and inventory levels on the basis of a large sample drawn from the probability distribution of production with prespecified storage capacity. Finally, the probability distribution of consumption and grain prices associated with different levels of worldwide storage capacity is calculated.

Given the estimated quantities and prices which obtain with and without storage, the model estimates the economic and financial

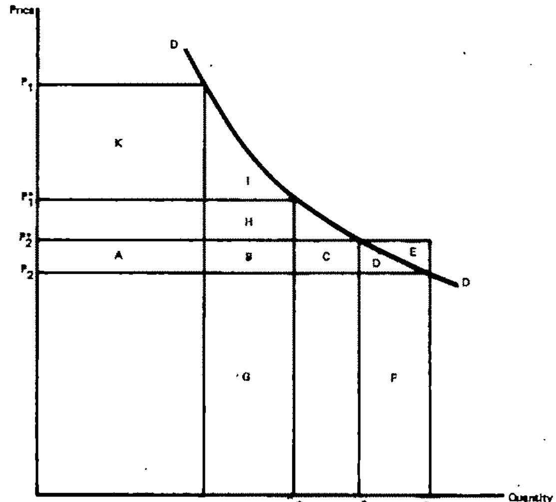

Figure 1. Storage benefits and losses

benefits or losses attributable to storage and the gains or losses experienced by producers and consumers each year. To obtain net variable benefits, variable storage costs are subtracted. The present value of the discounted stream of benefits and losses over a thirty-year period is then calculated. Finally, on the basis of a sample of 300 thirty-year sequences, the expected present value of the economic and financial benefits or costs (the producer and consumer gains or losses) and their respective standard deviations are estimated.

The calculation of annual gains or losses attributable to storage is illustrated in figure 1. The demand curve for grain is represented by DD; Q_2 is the level of production in a year of plenty. A quantity, $Q_2 - Q^*_2$, is placed in storage; Q_1 represents the level of production in a year of poor harvests; $Q^*_1 - Q_1$ is released from storage. In a year of plenty, the prices are P_2 without, and P^*_2 with storage. In a year of poor harvests, the prices are P_1 without and P^*_1 with storage.[1]

The financial (or storage operator's) gains or losses are straightforward. Assuming that purchases for or sales from storage are valued

---

[1] A single unique price corresponding with any level of production and storage activity presupposes that the trade can correctly anticipate the actual levels of production and quantities of grain going into or being released from storage. This presupposition implies, among others, that the storage operations are administered by a public authority whose primary objective it is to stabilize prices rather than to maximize profit. In the absence of unique price anticipations, the distribution of benefits (or losses) between consumers, producers, and storage operator could be quite different than those estimated by the model used in this study.

Table 1. Summary of Storage Benefits or Losses

	Benefits (+) and Losses (−)
Year of accumulation of stocks	
Consumer benefits	−A − B − C − D
Producer benefits	A + B + C + D + E
Financial benefits	−F − D − E
Economic benefits	−F − D
Year of release of stocks	
Consumer benefits	K + I
Producer benefits	−K
Financial benefits	G + B + H
Economic benefits	G + B + H + I

at the market price, the cost of grain put into storage is $P^*_2(Q_2 - Q^*_2)$ (designated as areas $F + D + E$ in fig. 1). Similarly the revenue from the grain taken out of storage is $P^*_1(Q^*_1 - Q_1)$ (designated as areas $G + B + H$ in fig. 1). Producer gains or losses are also straightforward. When grain is put into storage, producers sell the same amount of grain but at a higher price. Their gain is $(P^*_2 - P_2)Q_2$ (designated as areas $A + B + C + D + E$ in fig. 1). Similarly, when grain is taken out of storage, producers receive a lower price; their loss is $(P_1 - P^*_1)Q$ (designated as area K in fig. 1).

Consumer gains or losses and, hence, economic gains and losses can be measured in terms of consumer surplus. Consumers' losses are of two kinds when grain is withdrawn from the market. They pay a higher price for the grain which they do consume with or without storage (areas $A + B + C$ in fig. 1), and they are deprived of the amount of grain which is stored. Applying the consumer-surplus concept, the consumer loss due to the decline in consumption is measured by area D in figure 1. Similarly, when grain is withdrawn from storage, consumers experience a cost saving on the grain which they consume with or without storage (designated by area K in fig. 1). The additional grain consumed as a consequence of storage is measured by area I in figure 1.[2]

The benefits (+) or losses (−) which accrue to different groups in any year from storage activities, expressed in terms of the areas designated in figure 1, are summarized in table 1. Consumer benefits, financial benefits (the benefits to the storage operator), and economic benefits are always negative in years when stocks are accumulated and positive in years when grain is released from storage. Producers always gain when grain is put into storage and always lose when grain is released from storage. The present value of variable benefits depends on the difference between gains and losses in years of storage activity, the time elapsed between storage operations, the discount rate and variable storage costs. The present value of total net benefits also depends on the cost of constructing storage facilities.

Data and Parameters

World production is assumed to have a mean value of 350 million metric tons and to vary in the range of 314 to 386 million tons in accordance with a triangular probability distribution.[3] The mean value roughly corresponds with the trend value of production in 1972–73, and the interval on either side of the mean corresponds to approximately 2.5 standard deviations, the value of which (14 million tons) has been estimated on the basis of past deviations about the long-run trend in world wheat production (Steele, table 3).

The function chosen to represent the demand for wheat consists of two linear segments kinked at the point of mean world production. The parameter values of the two linear segments are specified to give a lower price elasticity in the range of short supplies and a higher elasticity in the range of abundant supplies. There are several plausible reasons why this should be a reasonable specification. Observed demand may reflect buying and selling for storage as well as current consumption. Under certain circumstances, private firms and governments may accumulate inventories when supplies are short and dispose of these inventories in times of plenty. When supplies are short and a large proportion of the population lives at the margin of minimally adequate nutrition, governments can be expected to (and actually do) attempt to maintain the consumption of the poorest segments of the population through increased purchases and distribution of food grains on concessional terms. Consequently, the price rises sharply in the face of reduced supplies. On the other hand,

[2] The consumer surplus concept as applied in this paper is widely used in analyzing the impact of trade, taxation and price policies. It is at best an approximation device. For a discussion of the restrictive assumptions underlying the use of the concept and the possible errors, see Samuelson (1963).

[3] The simulation model is currently reprogrammed to accommodate several alternative probability density functions.

when supplies are plentiful and the price comes within the range where it is profitable for wheat to be used in livestock feeding, this addition to the demand for direct consumption tends to increase the demand elasticity. Recent sharp increases in price in response to relatively small reductions in anticipated supplies provides some empirical evidence in support of the hypothesis that demand is very inelastic when supplies are short (UN, p. 6).

The precise demand function used in the initial simulations is as follows:

$$\begin{aligned} p &= 1374.5 - 3.57q \qquad q \leq 350 \\ p &= 541.5 - 1.19q \qquad q > 350, \end{aligned}$$

where p is the price of wheat per ton and q is the quantity in millions of tons. The elasticity at the midpoint of the segment corresponding with short supplies (332 million tons) is -0.15 and that at the midpoint of the segment corresponding with long supplies (368 million tons) is -0.24.[4]

The variable storage cost (loading and unloading, pest control, and electricity) is estimated at \$2 per ton. The discount rate is assumed to be 8%. The present value of the investment in storage silos is assumed to be \$50 per ton of storage capacity. The present cost of constructing new storage facilities is approximately \$150 per ton of capacity. However, due to the existence of a large underutilized capacity, it is assumed that additional investment will be required only to augment and to replace existing capacity and that construction will be spread out over many years.

The basic simulations consider storage capacities of 5, 10, 20, and 30 million tons (30 million tons corresponding roughly to two standard deviations of world production). Storage rule A provides that production in excess of 355 million tons is put into storage (to the extent that there is vacant capacity). When production is less than 345 million tons, grain is released from storage to the extent of the deficit (or to the extent of available stocks in storage). Storage rule B differs from storage rule A in so far as grain is released from storage only when production is less than 335 million tons.

The Effects of Storage Activity

The results presented below are based on simulating production and storage activities for 300 sequences, each consisting of thirty years. The observed frequency distribution of production of a sample of this size closely approximates the postulated probability distribution. Similarly, the sampling error of the expected values and the standard deviations of the estimated variables is small.[5]

Stabilization Effects

Table 2 summarizes the effects of storage activity on the stabilization of consumption and price. Several generalizations are possible. Storage can effectively reduce the probabilities of extreme events. For any given level of storage capacity, rule B gives far better insurance against extreme shortfalls of grain availability for consumption and high prices than rule A. Additional increments of storage capacity result in diminishing marginal reductions of the probability of being caught short.

Benefits and Costs

Table 3 presents the expected present value of benefits (+) or costs (−) over a thirty-year period of storage operations. Several noteworthy conclusions emerge. Storage benefits to the economy are low or negative and rapidly decline or turn negative beyond initial low levels of storage capacity. The reason for this is that, as the storage levels increase, there is less turnover in storage and grain is held for longer periods. The cost of time (interest) increasingly dominates the gross benefits which accrue from buying grain when its value is low and selling it when its value is high. As for the net benefits, the amortization cost per ton rises as the utilization of the storage capacity decreases.

Large benefits accrue to consumers, while producers pay a high price for stabilization. However, these gains and losses reach a plateau, as incremental storage capacity is increasingly less utilized. Moreover, the additional grain is stored for longer periods of time, until ultimately the discounting factor comes to dominate the gains or losses from price changes for consumers (or producers).

[4] As a first approximation, the average price elasticity was assumed to be −0.2, based on the analysis of elasticities by major countries, reported by Rojko.

[5] In estimating the present value over a thirty-year period, stocks in storage in the last year are valued at the expected price. The initial inventory is always assumed to be zero. No attempt was made to establish an optimum sample size. In view of the low computing costs, it was simply decided to use a sample large enough to yield a low sampling error.

Table 2. Probability Distributions of Wheat Consumption and Price

Quantity	Price	Without Storage	Storage Rule A: Storage Capacity (million tons) 10	20	30	Storage Rule B: Storage Capacity (million tons) 10	20	30
(million tons)	($/ton)	Probability (%)						
<324	>219	3.9	1.9	1.2	0.9	1.1	0.5	0.5
324–332	188–219	9.7	6.6	5.7	4.6	6.1	3.1	1.6
332–359	115–188	57.7	72.3	79.3	85.2	70.1	77.6	82.1
359–368	104–115	15.3	10.8	8.3	5.4	12.5	10.8	8.8
>368	<115	13.4	8.4	5.5	3.9	10.2	8.0	7.0
Mean price:	($/ton)	140	137	136	135	138	138	138

The high standard deviations of the present value of the costs of and benefits from storage over a thirty-year period illustrate the risky nature of investment in storage and the folly of using a particular observed sequence of yearly production levels (often of much less than thirty-years' duration) to predict the effects of storage operations. With an 8% discount rate, the sequence of good and bad harvests, particularly during the first years following the investment decisions, can drastically change storage benefits. Even if the expected storage benefits are positive, the chances are high that the investment will not pay off. Could this be a reason for not expecting the private trade to engage in large buffer stock operations?

While, as we have seen earlier, storage rule B gives higher protection against extreme shortfalls, storage rule A leads to greater expected economic benefits (or lower costs). However, even if rule A is followed, buffer stock operations cannot be justified on the grounds of expected economic benefits, except when they are operated on a very small scale, e.g., 5 to 10 million tons (about one-half of the standard deviation).

Since the distribution of gains and losses between consumers and producers is of great significance in assessing the politics of stock policies, it is interesting to note that rule B diminishes this conflict. Since grain is taken out of storage only at times of extreme shortage, grain is stored for long periods. Consequently, the discounting factor comes to dominate producer losses resulting from unfavorable price effects.

The annual, amortized benefits or costs corresponding with the expected present values

Table 3. Present Values of Storage Benefits

Type of Benefit[a]	Storage Rule A: Storage Capacity (million tons) 5	10	20	30	Storage Rule B: Storage Capacity (million tons) 10	20	30
	$ million						
Gross economic benefits	288	392	336	179	−5	−389	−865
	(245)	(424)	(648)	(834)	(451)	(739)	(955)

Consumer benefits	4909	8068	11230	12310	−2377	1675	−55
Producer benefits	−4820	−7800	−10604	−11477	−2226	−1365	461
	(2549)	(4323)	(6388)	(7371)	(3367)	(5105)	(6341)
Proportion of capacity utilized	0.156	0.135	0.107	0.090	0.088	0.071	0.061

Note: Values in parentheses are standard deviations.
[a] Gross economic benefits = financial benefits + consumer benefits + producer benefits.
Net benefits = gross benefits − cost of investment in storage facilities.

Table 4. Annual Benefits from Storage Activities

	Storage Rule					
	A			B		
	Storage Capacity (million tons)			Storage Capacity (million tons)		
Type of Benefit	10	20	30	10	20	30
	\$ million					
Gross economic benefits	35	30	16	−0.4	−35	−77
Net economic benefits	−10	−59	−117	−45	−123	−210
Gross financial benefits	11	−26	−58	−14	−62	−113
Net financial benefits	−33	−115	−191	−58	−151	−246
Consumer benefits	716	988	1093	211	149	−5
Producer benefits	−693	−942	−1019	−198	−121	41

reported in table 3 are shown in table 4. To the extent that the benefits are negative and a burden to the world economy, these values can be interpreted as insurance premiums which would need to be paid for achieving stabilization beyond the level at which expected direct gains exceed storage costs.

More stability and less uncertainty can be justified on several grounds. First of all, for grain producers more stable prices can yield more stable incomes, unless the ups and downs of their harvests are positively correlated with world prices. For low income consumers, more stable food grain prices may significantly stabilize effective incomes. Both groups may therefore put a positive value on stabilization of food prices. More significantly, perhaps stabilization might produce positive macroeconomic effects when sharply higher food prices push up negotiated wages, while equivalent reductions in food prices do not lead to wage reductions. Finally, our cost-benefit calculus has not taken into account possible positive output effects and better resource allocation decisions related to more stable food grain price anticipations.

To put the numbers in table 4 into better perspective, it should be noted that the expected total value of world wheat production is \$48 billion (350 million tons × \$140). A 20 million-ton program, operated under rule B and giving a high degree of protection, would have an annual expected cost of \$150 million for the storage operator. Consumers experience an equivalent gain. With average consumption at 350 million tons, consumers could be taxed annually at the rate of 50¢ per ton to cover the loss of the storage operation. This would seem a small premium, for which the consumer would be fully compensated by his expected gains from storage, neglecting completely the benefit he derives from more stable food prices. Producers would have an expected loss of 35¢ per ton. This loss may be a small price to pay for greater price stability.

Cost Effectiveness

Figure 2 illustrates the annual cost (or benefit) of reducing the probability of consumption shortfalls below 332.5 million tons. Without storage, the probability of consumption being less than 332.5 million tons is 13.6%. Several observations may be made. For any given storage level, rule B provides more protection than rule A. The marginal cost of protection increases rapidly for higher rates of protection. For instance, under rule A, at the rate of protection of 4% (i.e., a 9.5% chance instead of a 13.5% chance of having less than 332.5 million tons), an additional 1% of protection would cost approximately \$5 million. At the rate of protection of 9%, an additional 1% of protection would cost \$155 million. For very low rates of protection, rule A is more cost-effective than rule B, but for high rates of protection, rule B is more cost-effective than rule A. For instance, if 9% protection were desired, a storage level of 15 million tons, operated under rule B, could be sustained at an average annual economic cost of 90 million tons. Equivalent protection could be bought under rule A, only with a storage capacity of nearly 50 million tons and at an average annual economic cost of \$240 million.

Sensitivity to Assumed Demand Functions

While the stabilization effect of storage levels and storage rules is unrelated to the parameters of the demand function, the costs and

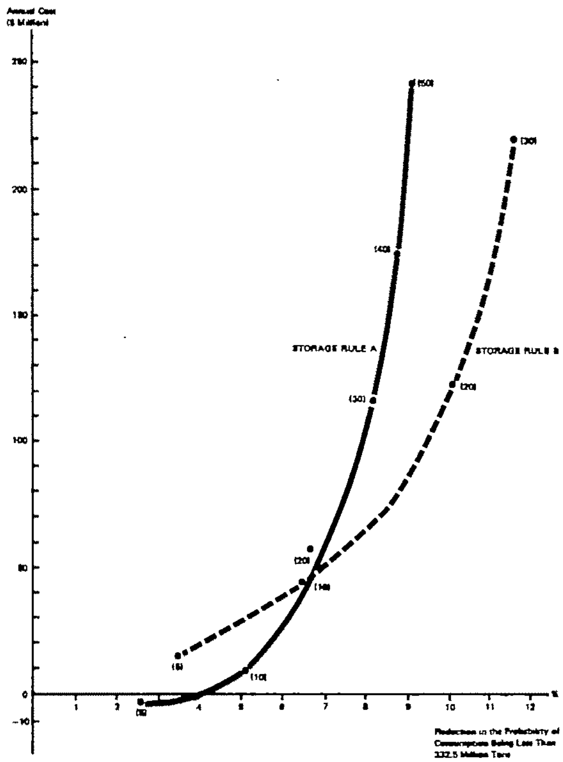

Figure 2. Cost effectiveness of storage operations (storage capacity shown in parentheses)

benefits can be expected to be sensitive to the assumed demand parameters.

Table 5 gives the annual benefits or costs of storage with a demand function which is more elastic for supplies in excess of 350 million tons. The elasticity of the new demand function is −1.0 at the point corresponding to 368 million tons as compared with −0.24 for the initial function. The respective prices at the same point are \$120 and \$103. A more elastic demand function in the range of long supplies does not change the economic and financial benefits very much. However, the gains to consumers and losses to producers are sig-

Table 5. Annual Benefits from Storage Activities with Higher Demand Elasticity for Long Supplies

	Storage Rule					
	A			B		
	Storage Capacity (million tons)			Storage Capacity (million tons)		
Type of Benefit	10	20	30	10	20	30
	\$ million

Consumer benefits	2518	3686	4249	1135	1421	1385
Producer benefits	−2474	−3583	−4114	−1111	−1375	−1329

Note: The assumed demand curve: $q < 350, p = 3003.29 - 8.22q$
$q > 350, p = 541.50 - 1.19q$.

nificantly higher, since withdrawal of grain from the market for storage barely increases the price.

Table 6 shows the results obtained for a demand function which is more inelastic within the range of short supplies. Specifically, the new demand function has an elasticity of −0.10 at the point corresponding to 332 million tons as compared with −0.15 with the initial function. The respective prices at the same point are \$275 and \$189. The economic and financial benefits here turn out to be very sensitive, making it extremely profitable to invest in buffer stocks. But again it is noteworthy that the storage impact on gains and losses by consumers and producers is particularly sensitive to the assumed shape of the demand function.

Food Aid and Food Stocks

In some quarters it is argued that separate food grain stocks should be held to assist poor nations afflicted with unforeseen food shortages. Presumably such stocks would have no adverse effects on producers, provided that without these stocks, there would be that much less food aid. Hence, separate food aid stocks may be politically more palatable.

Alternatively, a policy which aims at assuring food aid at a given level when needed and at the least possible cost, would not separate food aid stocks from other stocks. With such a food aid objective, it would be desirable to hold larger stocks and the value of these stocks would be higher.

As an illustration of the impact of food aid on stocks and vice versa, the results obtained from the simulation using different demand functions can be reinterpreted. The difference between the more inelastic and more elastic demand functions, within the range of less than average production (i.e., 350 million tons), could be assumed to reflect the demand for food aid related to worldwide scarcities of wheat.[6] The difference between the two demand functions is the amount of wheat given as food aid, q_A, i.e.,

$$q_A = -20 + .16p \qquad p > 125$$
$$q_A = 0 \qquad p < 125.$$

With food aid, the price of wheat associated with the worst likely production level (314 million tons) is \$427. In this case the quantity required for food aid is 48 million tons. When world production is 350 million tons or more and the associated price is \$125 or less, the amount of wheat required for food aid is zero.

Table 7 shows the additional gains and losses from storage attributable to the change in the demand function resulting from food aid. The additional economic benefits are sufficient to turn a net loss from storage (without food aid) at almost any level to a net gain for as much as 30 million tons of storage capacity, if operated under rule A. Even more significant, perhaps, is the large effect of storage on consumer gains and producer losses. Without storage, the added demand generated by food aid during times when supplies are short causes steep price rises. Hence, consumers (in the commercial market) register large losses

[6] The demand with aid is $p = 3003 - 8.22q$; the demand without aid is $p = 1374 - 3.57q$. For any given price (above \$125), the respective quantities are $365 - 0.12p$ and $385 - 0.28p$. The difference between the two equations reflects the demand for food aid.

Table 7. Annual Storage Gains and Losses Attributable to Food Aid

Type of Benefit	10	20	30	10	20	30
	$ million					
Net economic benefit	76	107	124	69	77	81
Net financial benefits	55	60	63	48	60	60
Consumer benefits	1800	2690	3156	924	1272	1390
Producer benefits	−1781	−2641	−3095	−913	−1254	−1370

while producers make large gains from the added demand for food aid. However, in this case, the large distributional effect of storage operations can be regarded as merely compensating consumers for losses and producers for gains incurred by them as a consequence of food aid.

Viewed in another way, storage reduces the cost of food aid. Without storage, the annual expected amount of food aid is about 8 million tons, the expected price is $223 and the expected total cost is $2.3 billion.[7] A scheme involving a storage capacity of 20 million tons, operated under rule A, would reduce the expected quantity of food aid to approximately 6 million tons, the expected price to $197 and the expected cost to $1.4 billion. The cost saving is, however, largely offset by storage costs. The average net financial savings per annum amounts to about $60 million.

International Allocation of Costs and Benefits

The major cause for the current inaction on international reserve stock policy is the conflict of interest among nations. While the simulation model described does not directly estimate the international allocation of costs and benefits, the estimates of the gains to consumers and losses to producers provide some useful insights into the international conflict with regard to food grain buffer stocks. On the basis of these direct average gains and losses, nations which are net importers would tend to gain whereas countries which are net exporters would tend to lose from large reserve stocks. There are, of course, other reasons why nations have different views about the desirability of holding reserve stocks.

[7] As noted earlier, under the postulated policy the actual amount of food aid (or at least the portion of food aid which is relevant to reserve stock policy) will range from zero to 48 million tons, depending on the market price of wheat.

The gains or losses which accrue to each country can be estimated by summing the gains and losses of its consumers and producers. The effect of storage on an individual country's consumers or producers can be estimated by multiplying the country's respective shares in world consumption and production by the respective worldwide gains or losses of consumers and producers. These shares for groups of countries derived from trend values estimated by the Food and Agriculture Organization for 1970 are shown in table 8.

Assuming the consumer gains and producer losses associated with a 20-million ton storage capacity, operated under rule B, the country benefits (+) or losses (−), exclusive of the direct net cost of the storage operation, are presented in table 9.

The data in table 9 illustrate why it is so difficult to reach an international agreement. If demand is perceived to be relatively elastic, the distribution of gains and losses is not likely to be a stumbling block to an international understanding about sizable buffer stocks, since all countries prefer greater stability. Conflict might arise, however, over the sharing of the high cost of the storage operation itself. If demand is perceived to be inelastic,

Table 8. Shares in World Wheat Consumption and Production

	Shares (%) in World Wheat	
Groups of Countries	Consumption	Production
U.S., Canada, Australia	9.3	18.0
Europe and Japan	19.8	16.1
USSR	25.8	29.5
Centrally planned economics (excluding USSR)	18.9	16.1
Developing countries	26.2	20.3

Table 9. Expected Annual Gains and Losses by Groups of Countries from Reserve Stock with a 20-Million Ton Capacity Operated under Rule B

Types of Gains (+) and Losses (−)	Demand (1)	Demand (2)
	——$ million——	
Combined producer and consumer benefits by groups of countries		
U.S., Canada, Australia	−8	−115
Europe and Japan	10	60
USSR	3	−37
Centrally planned economies (excluding USSR)	9	48
Developing countries	14	93
Benefits from storage operations	−151	−91
Total benefits	−123	−42

Note: Demand (1) refers to the initially assumed demand function (elasticity = −0.15 when quantity = 332 million tons) and Demand (2) refers to assumed more inelastic demand when supplies are short (elasticity = −0.1 when quantity = 332 million tons).

the exporting countries might question the very desirability of holding buffer stocks, no matter who pays for them. In particular, farmer lobbies might present a strong case against stocks. While the expected annual direct net loss to the exporting countries is $115 million, their producers might be expected to suffer a loss of $248 million.

Estimates such as are reported in table 9 could provide a rational basis for negotiating cost-sharing schemes. It is beyond the scope of this paper to recommend any particular cost-sharing formulas, particularly since they need not be based exclusively on equalizing benefits. They could, for instance, be partially based on ability to pay, in the context of international aid programs to developing countries. In any case, more precise up-to-date information and better models which account for established trade barriers among countries are needed to replace the illustrative numbers presented in this paper.

Limitations of the Model

Several limitations of the present simulation model for projecting the consequences of storage operations for the world wheat economy have already been noted. These limitations and some additional qualifications are now briefly summarized. Suggestions on ways to improve any future analysis of this kind are also provided.

The storage rules are crude. More refined storage rules could increase the benefits (or reduce the costs) of operating storage schemes at any level. However, in my judgment, the order of magnitudes of stabilization and benefits and costs would not be much different with optimal storage rules and hence, the basic conclusions derived on the basis of crude storage rules would not change. In any case, it is questionable whether the implementation of any storage policy would exactly follow sophisticated storage rules.

The sum of the justifiable storage activity in different locations around the world would be larger than the amount of storage deemed sufficient on the basis of the simulation of storage requirements in a unified world market. Clearly, when surplus production in one location cannot be used for reducing production shortages in other locations, there is greater justification for stabilizing local production fluctuations through storage operations.

Annual production has been assumed to be a random independent variable. If production is characterized by systematic cycles, the stabilization effect of a given level of storage capacity will be less than if year-to-year production is not correlated, given the storage rules suggested in this study. However, if cycles could be predicted with any degree of reliability, storage rules could be designed which would lead to higher economic and financial benefits than are obtainable from storage rules appropriate to an environment of random, independent fluctuations for any desired fixed level of stabilization.

A static model, which abstracts from changes over time in demand and supply conditions, as used in the current study, is also relevant to projections in a dynamic world, but only under certain restrictive assumptions. One set of such assumptions is that the slope of the demand function does not change while shifting to the right, that expected production shifts at the same rate as the demand function, and that the absolute standard deviation of production remains the same. These are plausible but not sufficiently tested assumptions. Demand for food grain might become more inelastic as a consequence of higher per capita incomes over time; technological progress might make it possible to produce larger outputs without increasing costs and the relative standard deviation might decline as more production comes from irrigated land.

However, with different assumptions about trends, the results presented in this paper would need to be modified in a predictable

way. Constant elasticity over time implies that the slope of the demand function declines over time. Hence, the benefits from storage would decline for a fixed range of production and storage capacity. Alternatively, if the absolute standard deviation of production increases over time, storage capacity would have to be increased proportionally to attain a desired level of stabilization. If supply grows faster than demand, and, therefore, there is a downward trend in price, storage benefits would be reduced. Conversely, if demand grows faster than supply, and, therefore, price rises over time, benefits from storage would obviously be higher than calculated in the absence of a price trend.

The foregoing model has assumed that mean production would be the same with and without storage. This is clearly a strong assumption, given that stabilization decreases the expected price and its variability (as long as we postulate a concave demand function). While there is some evidence that production responds positively to a decline in price variability (Moscardi; Reutlinger 1963) and negatively to a decline in the expected price, it is difficult even to predict the direction of bias from failing to consider the expected supply response to storage without much more empirical evidence. Nevertheless, it would be worthwhile to construct models which explicitly account for the interaction of supply and demand.

Summary and Conclusions

The paper describes a simple simulation model for estimating the effects of operating a buffer stock scheme in the context of a unified world market. While the model is static, it can, under restrictive assumptions about trends in demand and supply and the coefficient of variation in production, be used to analyze the projected impact of alternative levels of storage activity. The aim of the storage rules is to stabilize available supplies. Since the expected supply is assumed to be the same with and without storage, the storage rules also implicitly imply a desired level of price stabilization.

Illustrative runs of the model yield some interesting conclusions. In the range of plausible demand elasticities, optimal levels of buffer stocks in terms of net benefits are likely to be too low to afford reasonably satisfactory protection against extreme shortfalls of grain and extremely high prices.

A storage scheme which operates with "insurance-oriented" storage rules under which grain is released only in years of extremely poor harvests can be very cost-effective for achieving a high level of protection against extreme shortfalls in grain supplies. With such storage rules, 20 million tons of storage capacity could reduce the probability of grain supplies being short by more than 5% of the mean from 13.6% to 4.6% and could reduce the probability of a shortfall in excess of 7.5% from 4% to 0.5%.

The annual negative net benefits, i.e., the annual insurance premium of an insurance-oriented program would be of the order of $50 million to $150 million, in the range of demand elasticities considered. In terms of the world's expected wheat production, this amounts to an insurance premium of the order of 20¢ to 50¢ per ton per annum.

The gains to consumers and the losses to producers can be sizable. Hence, it is very important to assess the distributional impact of storage schemes. The standard deviation of the expected gains or losses from the buffer stocks is very large, indicating the high risk of investments in such stocks arising from the progression of good and bad years in different thirty-year "samples" from a probability distribution of production.

If food aid between countries and within countries is a deliberate policy objective, the added demand during years of poor harvests has a significant effect on stock requirements and the benefits to be derived from operating buffer stocks.

Welfare Implications of Stabilizing Consumption and Production

Abraham Subotnik and James P. Houck

Some economists are now urging the use of buffer stocks to help stabilize farm and food prices. Moreover, price stabilization has been shown to be socially beneficial from a theoretical point of view. Our purpose is to analyze the welfare implications of stabilized consumption and production and to compare them with the known implications of stabilized prices. It is shown that stabilized consumption is the least beneficial in its welfare implications. The relation between the gains from stabilization and the size of buffer stocks necessary to achieve stabilization also is analyzed. Finally, the presentation is extended to cover instability due to fluctuations in export demand.

Key words: buffer stocks, consumption stabilization, export stabilization, price stabilization, production stabilization, welfare gains.

Market stabilization has become an important issue in the controversy over establishing reserve stocks of grains. Among others, Cochrane has strongly urged the establishment of buffer stocks of agricultural products to help stabilize prices. However, Cochrane and others primarily concerned with public policy do not support their position from a theoretical point of view. Their objective seems to be the stabilization of prices as a goal in itself. Yet from a purely theoretical point of view, Massell has used conventional consumer and producer surplus analysis and some previous results obtained by Waugh (1944, 1961) and Oi to show that price stabilization with a buffer stock is socially beneficial compared to the free market. These particular results were obtained assuming that supply reacts instantaneously to a change in market prices. Similar results were obtained more recently by Turnovsky who analyzed the welfare implications of price stabilization under different assumptions concerning the behavior of supply.

Therefore, advocates of buffer stocks which stabilize prices could justify their positions theoretically. But if price stabilization can be justified in terms of social welfare, might it also be true that stabilizing other market variables will be even more beneficial? If maximizing social welfare is the policy objective, there is no a priori reason why stabilizing the quantities demanded or supplied should not be appropriate alternatives to price stabilization.

The main purpose of this paper is to analyze welfare implications of stabilized consumption and production and to compare them with welfare implications of stabilized prices which are already known. The focus of the analysis is on agricultural products where farmers cannot adjust instantaneously to changes in market prices. Therefore, producers' reaction to changes in expected prices and expectations are assumed to be "rational" within the context developed by Muth. This implies that, in the short run after planting decisions have been made, supply is completely inelastic. As a by-product of this analysis, the relation between the gains from stabilization and the size of the buffer stocks necessary to achieve the stabilizing goal also is shown. Finally, the analysis is extended to cover instability due to fluctuations in export demand.

Method of Analysis

In this discussion, the quantity supplied in any marketing period does not depend on current price but on expected price as visualized by producers at the time when their production decision was made. The basic model is

$$(1) \qquad \begin{aligned} D(P_t) &= \alpha_0 - \alpha_1 P_t + u_t \\ S(P^*_t) &= \beta_0 + \beta_1 P^*_t + v_t, \end{aligned}$$

Abraham Subotnik is on the faculty of industrial and management engineering at Technion, Israel Institute of Technology, Haifa, Israel, and James P. Houck is with the Department of Agricultural and Applied Economics, University of Minnesota.

Scientific journal series paper 9253 of the Minnesota Agricultural Experiment Station.

where D and S are the quantities demanded and supplied, P is the market price, and u and v are random elements affecting demand and supply. It is assumed that the error terms are independent with finite variances, σ_u^2 and σ_v^2; P^*_t is the expected price visualized by producers when production decisions for the marketing period t are made.

"Rational" price expectations, as Muth defines the term, means that producers decide on output according to the expected equilibrium price that would be obtained from the solution of the structural model. It follows that the expected price is

$$(2) \qquad P^* = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1}.$$

In the absence of stabilizing intervention, the competitive market solutions are

$$(3) \qquad P_e = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1} + \frac{u_t - v_t}{\alpha_1}$$

and

$$Q_e = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} + v_t.$$

The effects of any stabilizing scheme are measured in terms of consumers' and producers' surplus as compared to free market behavior.[1] The areas representing the consumers' and producers' surplus (gains or losses) are obtained as follows. Let P_e be the free market equilibrium price, P_s be the market price under any particular stabilization scheme, D_e and S_e be the free market equilibrium demand and supply respectively ($D_e = S_e = Q_e$), $D(K)$ and $S(K)$ be the demand and supply functions respectively for any of the stabilization schemes considered, and $K = P_s$, D_s, or S_s, indicating a price stabilization, consumption stabilization, or supply stabilization scheme, respectively. Then the consumer gains (or losses) due to any scheme are

$$(4) \quad G_c = \int_{P_s}^{P_e} D(P)dP = \int_{P_s}^{P_e} (\alpha_0 - \alpha_1 P)dP = 1/2(P_e - P_s)(D_e + D_s).$$

Similarly, the producers' gains (or losses) are

$$(5) \quad G_s = \int_{P_e}^{P_s} S(P)dP = \int_{P_e}^{P_s} (\beta_0 + \beta_1 P)dP = 1/2(P_s - P_e)(S_s + S_e).$$

The total gain or losses from any stabilizing scheme are

$$(6) \qquad G = G_c + G_s.$$

The levels at which the various market variables (price, quantity demanded, and quantity supplied) are stabilized correspond to their expected values under a free market system. Thus, stabilization is aimed at eliminating the free market randomness in the variable being stabilized.

Since welfare gains (or losses) measured in equations (4), (5), and (6) relate stabilization to randomly disturbed free market situations, these measured gains (or losses) are themselves random. Therefore, we compare the expected values of welfare gains (or losses) derived from various stabilization schemes.

The reason for dealing with a static model as in equation (1) is only for convenience. The addition of demand and supply shifters does not change the nature of most results obtained. Whenever a changing stabilized variable through time has an impact on the results, it is mentioned and analyzed.

The Analysis of Stabilizing Schemes

Price Stabilization

Price is assumed stabilized at

$$(7) \qquad P_s = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1}.$$

Hence, the market quantities demanded and supplied, and the change in government stocks are

$$D(P_s)_t = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} + u_t,$$

$$(8) \qquad S(P_s)_t = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} + v_t,$$

and

$$\Delta G_t(P_s) = v_t - u_t.$$

When these solutions are compared to the free market solution, the expected gains from price stabilization by consumers, producers, and in total are

$$(9) \qquad EG_c(P_s) = \frac{1}{2\alpha_1}(\sigma_u^2 - \sigma_v^2),$$

[1] The drawbacks of measuring welfare gain or loss by means of various areas associated with demand and supply functions are well known and have been dealt with extensively elsewhere. Those arguments will not be repeated here but should be kept in mind.

$$EG_s(P_s) = \frac{1}{\alpha_1}\sigma_v^2, \tag{10}$$

and

$$EG(P_s) = \frac{1}{2\alpha_1}(\sigma_u^2 + \sigma_v^2). \tag{11}$$

Producers are not affected by demand instability while consumers are affected by both sources of instability. Graphically, this is shown in figures 1 and 2.

When only demand is unstable and D_1 and D_2 are equally likely, then the free market solutions are at B and E in figure 1. With no price stabilization, the producers either lose the amount $ABCD$ or gain $CDEF$. Since on average they neither lose nor gain with a free market, it follows that by stabilizing price at P_s they also do not lose or gain. On the other hand, consumers will gain the area of $ABCG - CHFE$ from stabilized prices. The government will buy HD or sell DG.

When only supply is unstable and S_1 and S_2 are equally likely, then free market solutions are B and G in figure 2. Here the loss in consumers' surplus is the area of $FGCE - ABCE$ and the gain in producers' surplus is the area of $EFGH - ABED$. The government will either sell CD or buy CH. There is a simple relation between the total expected social gains and the variance of changes in government stocks, defined for a price stabilization scheme as $\sigma^2(P_s)$. Since $\sigma^2(P_s) = \sigma_u^2 + \sigma_v^2$, then

$$EG(P_s) = \frac{1}{2\alpha_1}\sigma^2(P_s). \tag{12}$$

Stabilization of Consumer Demand

Assume that the quantity demanded is stabilized at the expected free market equilibrium

$$D_s = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1}. \tag{13}$$

The stabilization of consumer demand implies that the market price, the quantity supplied, and changes in government stocks are

$$P(D_s)_t = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1} + \frac{1}{\alpha_1}u_t,$$

$$S(D_s)_t = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} + v_t, \tag{14}$$

and

$$\Delta G(D_s)_t = v_t.$$

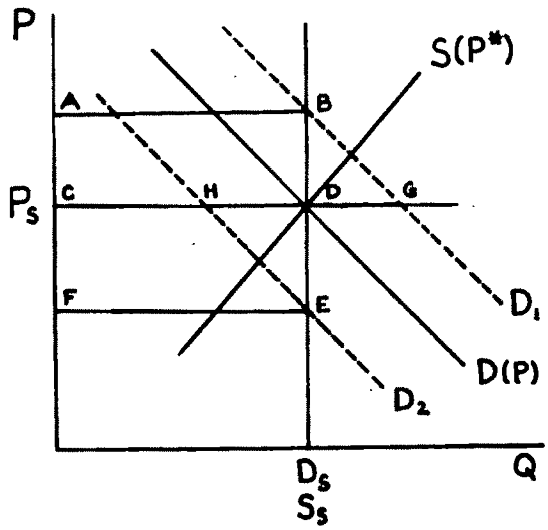

Figure 1. Welfare gains when demand is unstable

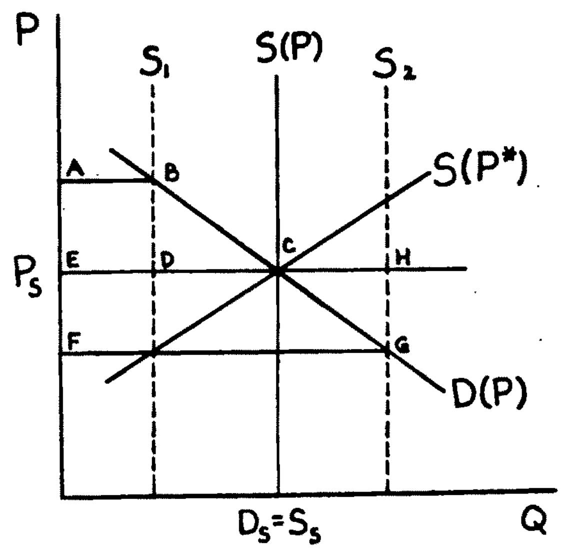

Figure 2. Welfare gains when supply is unstable

The government will buy or sell stocks to stabilize demand only if supply is unstable.

The stabilization of consumer demand produces these expected gains

$$EG_c(D_s) = \frac{-1}{2\alpha_1}\sigma_v^2, \tag{15}$$

$$EG_s(D_s) = \frac{1}{\alpha_1}\sigma_v^2, \tag{16}$$

and

$$EG(D_s) = \frac{1}{2\alpha_1}\sigma_v^2. \tag{17}$$

These gains are independent of demand instability.

Points B and E in figure 1 are free market equilibrium solutions for D_1 and D_2 respectively, when rational expectations apply. Such solutions do not require government intervention to satisfy the consumption target. Therefore, if consumption is stabilized and only demand is unstable, the free market solution will be the same as the stabilized solution. Since the solutions are the same, it follows that demand instability has no effect on consumer welfare. The graphical analysis of this scheme when supply is unstable is also shown in figure 2.

The variance of the change in government stocks is

$$(18) \qquad \sigma^2(D_s) = \sigma_v^2.$$

Hence,

$$(19) \qquad EG(D_s) = \frac{1}{2\alpha_1}\, \sigma^2(D_s).$$

Supply Stabilization

Next the supply target is assumed set at

$$(20) \qquad S_s = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1}.$$

Once producers have decided their level of production, supply forthcoming will depend only on that production decision and on the random elements affecting supply. Thus, when supply is stabilized and expectations are rational, government must buy and sell stocks according to total quantity supplied. But the price at which purchases and sales are made depends on the supply target. We return to this point later.

When the supply target is set at S_s, then the quantities demanded and supplied, the market price, and the change in government stocks are

$$D(S_s)_t = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} + \frac{\alpha_1}{\beta_1} v_t + u_t,$$

$$(21) \qquad S(S_s)_t = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} + v_t,$$

$$P(S_s)_t = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1} - \frac{1}{\beta_1} v_t,$$

and

$$\Delta G(S_s)_t = \left(1 - \frac{\alpha_1}{\beta_1}\right) v_t - u_t.$$

The expected gains generated by this scheme are

$$(22) \qquad EG_c(S_s) = \frac{1}{2\alpha_1}\left(\sigma_u^2 + \frac{\alpha_1^2 - \beta_1^2}{\beta_1^2}\sigma_v^2\right),$$

$$(23) \qquad EG_s(S_s) = \frac{\beta_1 - \alpha_1}{\alpha_1\beta_1}\sigma_v^2,$$

and

$$(24) \qquad EG(S_s) = \frac{1}{2\alpha_1}\left[\sigma_u^2 + \left(1 - \frac{\alpha_1}{\beta_1}\right)^2 \sigma_v^2\right].$$

A better understanding of these analytical results may be gained by geometrically examining the effects of demand and supply instability on measures of social welfare. In figure 1, only the effects of unstable demand are shown. The supply target is satisfied at S_s. If demand shifts to D_1, the free market equilibrium is at B, since S_s is supplied under the rational expectations assumption. Only at G is the price paid by consumers the same as that expected by producers and used in production planning.

To achieve a solution at G, the government must sell stocks, driving the price down to P_e. Similarly, if D_2 occurred, the free market solution would be at E. The government then would buy stocks driving the price up to P_e. If D_1 and D_2 are equally likely, the expected gains by consumers will be increased by the area of $ABCG-CFEH$ which is positive. On the other hand, it can be shown that expected producers' gains are $ABCD-CDEF = 0$.

The effects of supply instability are more complex. Although the effect of supply instability is beneficial in terms of the total expected gains, its differential effect on consumers and producers depends on the relative size of α_1 and β_1. When $\alpha_1 > \beta_1$, supply instability is beneficial for expected consumer gains and detrimental for expected producer gains. The opposite holds for $\beta_1 > \alpha_1$.

Figure 3 illustrates the effects of supply instability when $\alpha_1 > \beta_1$. In this case, the supply curve $S(P^*)$ remains constant; the random effects change only the quantity supplied after the production decision is made. Assume that a shift to either S_1 or to S_2 is equally likely. When S_1 is supplied, government acquires BE of stocks driving the price up to E. This is because E is the price at which producers would produce S_s if they could adjust output given the random disturbance which actually occurred. Similarly if S_2 is supplied, govern-

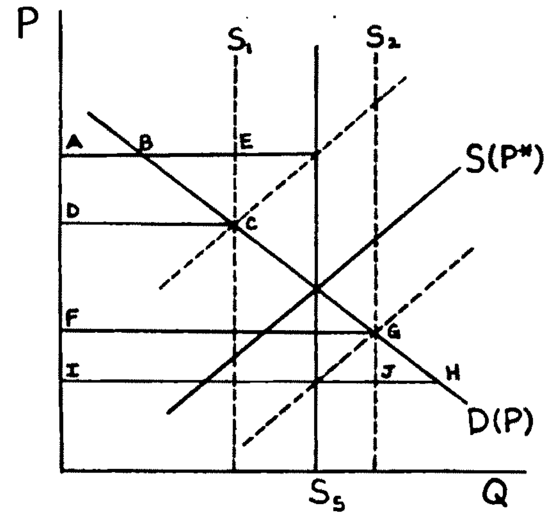

Figure 3. Welfare gains when supply is stabilized and $\alpha_1 > \beta_1$

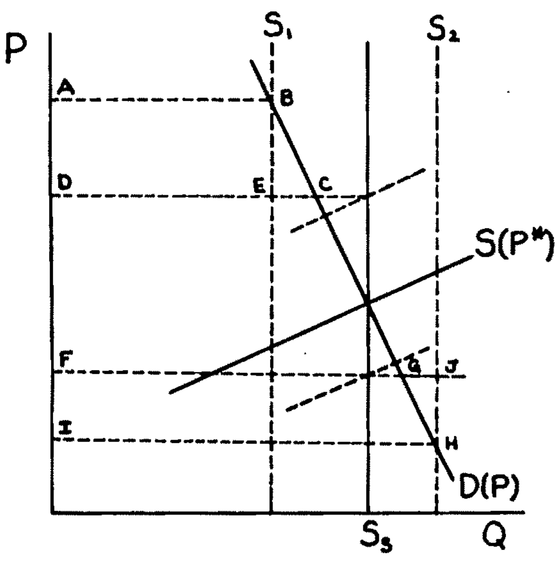

Figure 4. Welfare gains when supply is stabilized and $\beta_1 > \alpha_1$

ment will sell JH of stocks driving the price down to J. As a result, consumers' expected gains are $FGHI-ABCD$. Producers' expected losses are $FGIJ-AEDC$, and total expected gains are $BEC+GJH$.

Figure 4 illustrates the effects of supply instability when $\beta_1 > \alpha_1$. Assume S_1 and S_2 are equally likely. With S_1, the price which would induce producers to produce S_s (given their adjustment to the S_1 disturbance) is lower than the free market price. Similarly with S_2, the price which would induce production at S_s is higher than the free market equilibrium price.

It follows that if S_1 happens, government will sell EC stocks driving the price down to C. If S_2 happens, government will acquire GJ stocks driving the price up to G. As a result, consumers' expected losses are $HGFI-ABCD$, producers' expected gains are $FJHI-ABDE$, and total expected net gains are $BCE+GJH$.

Government intervention in supply stabilization may result in either increased or decreased price variability depending on the relative sizes of α_1 and β_1. Thus, either a deficit or a surplus in government expenditures can occur when considering a static model. In such a case, the expected deficit is $\frac{\sigma^2}{\beta_1^2}(\alpha_1 - \beta_1)$. When $\alpha_1 > \beta_1$, prices are destabilized, and a deficit will occur. When $\beta_1 > \alpha_1$, prices are more stable, and there will be a surplus. It is tempting to add or subtract this value from the expected social gains to arrive at a measure of net expected gains. In our view, this procedure is too restrictive for any real world application since equilibrium prices and quantities change through time because of systematic shifts in demand and supply.

While an expected budget loss at any given time depends on objective conditions at that time, the total budget situation, unlike the benefits and losses to society, depends on the previous behavior of equilibrium prices and quantities. Without all this previous data, it is difficult to integrate the budgetary aspects of these stabilization schemes. Therefore, this discussion is confined to the welfare implications of different stabilizing schemes without considering their budgetary implications.

The variance of changes in government stocks is

$$\sigma^2(S_s) = \left(1 - \frac{\alpha_1}{\beta_1}\right)^2 \sigma_v^2 + \sigma_u^2. \tag{25}$$

This variance is related to the expected social benefits as follows:

$$EG(S_s) = \frac{1}{2\alpha_1}\,\sigma^2(S_s). \tag{26}$$

Summary of Stabilization Schemes

Three stabilization schemes have been analyzed. The welfare implications of the different schemes do not depend on whether the system is static or whether equilibrium solutions change through time, if the demand and supply shifters are known with certainty. The

expected welfare gains at each point in time are independent of one another. On the other hand, the budgetary implications of the different schemes cannot be analyzed in the context of static models. They depend on the time path of the equilibrium prices and quantities.

Considering only the expected social gains and abstracting from budgetary considerations: if $\alpha_1 \geq 2\beta_1$, $EG(S_s) \geq EG(P_s) > EG(D_s)$, and if $\alpha_1 < 2\beta_1$, $EG(P_s) > EG(S_s) > EG(D_s)$. These results have a cost counterpart measured by the stocks needed by the government in order to carry out the different stabilizing schemes. Appealing to the Central Limit Theorem of statistics, we assume that the needed changes in government stocks are approximately normally distributed. This assumption becomes more realistic the larger the model and the more sources of instability are built into the system. It follows that in order to be effective in 95% of all possible cases, the government needs to hold about 1.96 times the standard deviation of stocks indicated under any particular scheme.

If a cost function for carrying stocks is known, then a price tag could be attached to each of the stabilizing schemes. But even if such cost functions are not known, the analysis at least provides a ranking of the different schemes according to their relative costs. These relative costs are directly related to the variance in government stocks associated with each scheme. It was shown that, for every scheme, the variance of the change in government stocks is proportional to expected social gains. Therefore, the storage costs involved can be ranked in the same order as the expected gains from the different stabilizing schemes. Therefore, if $\alpha_1 \geq 2\beta_1$, $\sigma^2(S_s) \geq \sigma^2(P_s) > \sigma^2(D_s)$, and if $\alpha_1 < 2\beta_1$, $\sigma^2(P_s) > \sigma^2(S_s) > \sigma^2(D_s)$. This shows that the more beneficial the scheme, the higher are the costs involved.

Stabilization Schemes When Foreign Demand is Unstable

The foregoing analysis may be extended to cover cases in which foreign trade adds an additional source of instability to the internal market. Hueth and Schmitz analyzed welfare implications of a price stabilization scheme when foreign markets are unstable and when internal supply reacts instantaneously to price change.

In this section, the welfare implications of the stabilizing schemes are analyzed when foreign markets are unstable and when internal supply reacts to a change in rational expectations. The demand for exports is assumed perfectly price inelastic but subject to random fluctuation. This facilitates the introduction of instability from foreign markets without losing generality from the results. Therefore, the level of exports will be reflected by

$$x_t = \bar{x}_t + \epsilon_t, \tag{27}$$

where $\bar{x}_t$ = expected levels of exports for time t known in t-1, and ϵ_t = random component of exports. It is assumed that ϵ_t is independently distributed of u_t and v_t and that its variance is finite at σ_ϵ^2. In addition, the country facing this fluctuating demand is assumed to be the only source of supply.

Following the earlier formulation of rational expectations, the model now becomes

$$\begin{aligned} D(P_t) &= \alpha_0 - \alpha_1 P_t + u_t, \\ S(P^*_t) &= \beta_0 + \beta_1 P^*_t + v_t, \end{aligned} \tag{28}$$

and

$$D(P_t) + x_t = S(P^*_t),$$

where because of rational expectations

$$P^*_t = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1} + \frac{1}{\alpha_1 + \beta_1} (\bar{x}_t). \tag{29}$$

It follows that the free market solutions are

$$D_E = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} - \frac{\alpha_1}{\alpha_1 + \beta_1} (\bar{x}_t) - \epsilon_t + v_t, \tag{30}$$

$$P_E = \frac{\alpha_0 - \beta_0}{\alpha_1 + \beta_1} + \frac{1}{\alpha_1 + \beta_1} (\bar{x}_t) + \frac{u_t - v_t + \epsilon_t}{\alpha_1}, \tag{31}$$

and

$$S_E = \frac{\alpha_0\beta_1 + \alpha_1\beta_0}{\alpha_1 + \beta_1} + \frac{\beta_1}{\alpha_1 + \beta_1} (\bar{x}_t) + v_t. \tag{32}$$

By assumption, all sources of instability are independent. Since demand and supply instability have been analyzed and since these effects are additive, we now focus on export instability separately.

It can be shown that, for all schemes analyzed in this paper (stabilized prices, domestic consumption, and production), export insta-

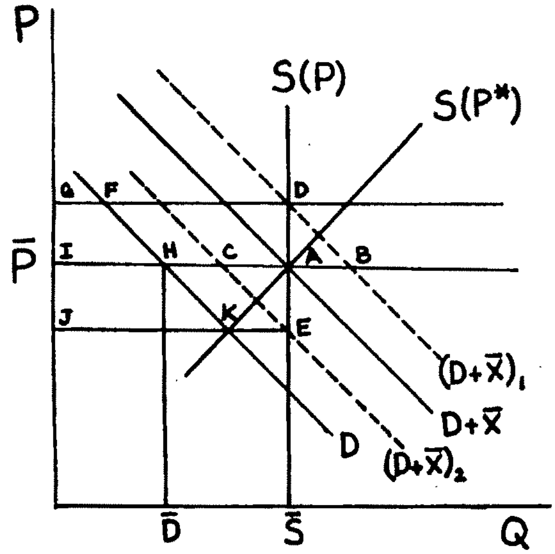

Figure 5. Welfare gains when exports are unstable

bility has the same effect. Consider figure 5 where $ED_E = \bar{D}$, $ES_E = \bar{S}$, $EP_E = \bar{P}$. The barred variables are the expected values of the endogenous variables. These expected values, in turn, are the levels at which consumption, production, and price, respectively, are stabilized.

Let $(D + \bar{x})_1$ be as likely as $(D + \bar{x})_2$. If price is to be stabilized, it will be set at $\bar{P}$. It follows that if $(D + \bar{x})_1$ occurs, government will sell the AB stocks driving the price down to $\bar{P}$. At the stabilized price, domestic consumption will be $\bar{D}$ and production will be $\bar{S}$. Similarly, if total demand shifts to $(D + \bar{x})_2$, government will buy AC stocks, and prices will settle at $\bar{P}$. At $\bar{P}$, domestic consumption and production remain at $\bar{D}$ and $\bar{S}$, respectively.

If production is stabilized, it will be at $\bar{S}$. If a random shift to $(D + \bar{x})_1$ happens, the government sells AB stocks. Domestic demand settles at $\bar{D}$ and price at $\bar{P}$. If the random shift is to $(D + \bar{x})_2$, the price will be raised to $\bar{P}$ as the government acquires AC stocks. Again, domestic demand settles at $\bar{D}$.

If domestic consumption is stabilized, it will be at $\bar{D}$. By the same reasoning outlined above, domestic consumption is stabilized at $\bar{D}$ only if the price is $\bar{P}$ and supply is $\bar{S}$. This is achieved by the government's either selling AB stocks or buying AC stocks. Consequently, when exports are unstable, all stabilization schemes analyzed exhibit the same effects on expected gains of producers and domestic consumers.

In terms of figure 5, the expected gains in consumer welfare are negative and measured by the area $HIJK - FGIH$. On the other hand, since supply becomes completely inelastic at its expected equilibrium level, the expected producer gains are zero because the gains ($IAJE$) equal the losses ($GDIA$). Analytically,

$$EG_C = EG = -\frac{1}{2\alpha_1}\sigma_\epsilon^2.$$

In this case, stabilization policies at home when exports are unstable become a burden only on domestic consumers. This is because, by stabilizing the internal market, the gains derived from avoiding higher prices are smaller than the losses derived from being unable to buy at lower prices. Hence, if exports are the only source of instability in the system, no stabilizing scheme will improve social welfare.

However, if we include welfare effects of stabilization on the importers, these results change. Returning to figure 5, it can be seen that in this broader case, expected consumer gains (domestic and foreign) become positive and are measured by $GDIB - ICEJ$. Expected producer gains do not change. Analytically, the total expected gains (domestic and foreign) from stabilization at home are

$$EG^T = \frac{1}{2\alpha_1}\sigma_\epsilon^2. \tag{33}$$

The world as a whole benefits from any stabilization scheme in a single exporting nation when export demand is unstable. The difference between world expected gains and domestic expected gains is the expected benefit which the importing country derives from stabilization by the exporter

$$EG^T - EG = \frac{1}{\alpha_1}\sigma_\epsilon^2. \tag{34}$$

This expected benefit is equal to the expected savings in import outlays due to stabilization by the exporter. This can be shown as follows:

$$M = (\bar{P} + \eta)(\bar{x} + \epsilon), \tag{35}$$

where M = import outlay and $\eta = \frac{\epsilon}{\alpha_1}$. When the internal market is not stabilized, the expected outlay becomes

$$EM = \overline{PX} + \frac{\sigma_\epsilon^2}{\alpha_1}. \tag{36}$$

On the other hand, when the internal market is stabilized, the expected outlay becomes

$$EM^* = \overline{PX}. \tag{37}$$

Therefore,

$$EM - EM^* = \frac{\sigma_\epsilon^2}{\alpha_1} \tag{38}$$

is the additional expected import outlay when the domestic market is not stabilized. It represents expected savings to the importing country due to market stabilization at home by the exporter.

These results indicate some trade policy issues which become relevant when stabilization schemes are considered. For example, the export nation might wish to eliminate export instability by contracting in advance with foreign countries. This, in turn, might require the administration of a new buffer stock or inventory management scheme in the importing countries. Alternatively, if importing countries are not willing to contract, the exporter might stipulate export quotas in advance. If no quotas or advanced contracting are possible, the domestic market might be stabilized and importing countries might be levied an amount equal to $\sigma_\epsilon^2/\alpha_1$. This result would benefit the exporter and lead to free market behavior in world markets.

Since export instability affects the expected welfare gains derived from each of the stabilization schemes identically, its occurrence does not alter the relative ranking of the schemes in terms of welfare gains or storage costs.

Summary

This paper presents analyses of welfare implications of the deliberate stabilization of either consumption or production and then compares those results with the welfare implications of stabilized prices which are already known. Supply is assumed to behave according to the rational expectation model. Unstable export demand also is added to the plausible, but abstract, theoretical models investigated.

The ordinal welfare ranking of these three schemes depends upon the relative size of the demand and supply price response coefficients.[2] In all cases, demand stabilization is the least beneficial in its welfare implications. To the extent that the operating costs of various stabilization schemes are directly related to the associated variance in government stocks, the ordinal ranking from high to low on welfare grounds is the same as the ordinal ranking of high to low on cost grounds.

[2] The rational expectation model does not result in exactly the same ranking of stabilization schemes as one in which producers react instantaneously to a change in market prices. In the latter case, the following holds. If $\alpha_1 > \beta_1$, $EG(S_s) > EG(P_s) > EG(D_s)$ and $\sigma^2(S_s) > \sigma^2(P_s) > \sigma^2(D_s)$. If $\beta_1 > \alpha_1$, $EG(D_s) > EG(P_s) > EG(S_s)$ and $\sigma^2(D_s) > \sigma^2(P_s) > \sigma^2(S_s)$.

Prices and Demands for Input Characteristics

George W. Ladd and Marvin B. Martin

Price of an input equals the sum of the money values of the input's characteristics to the purchaser; money value of each of an input's characteristics equals the input's yield of the characteristic multiplied by the money value of one unit of the characteristic. Demand for an input is affected by the input's characteristics. The themes are derived from a neoclassical firm model, in which the arguments of the firm's production function are quantities of input characteristics used, and from duals of linear programming blending problems. These themes are used to evaluate corn grades.

Key words: grades, hedonic prices, product characteristics.

For some analyses, it is adequate to assume product homogeneity, but the essence of some problems involves product heterogeneity. Among these latter are problems involving product differentiation, quality, and grades and standards.

We suggest taking a product characteristics approach to the study of product heterogeneity. This approach views a product as a collection of characteristics. Then product heterogeneity arises in various ways. Two products can possess different amounts of the same characteristics or one product can contain a characteristic that the other does not. Two products may contain two completely different sets of characteristics.

In this paper we apply the product characteristics approach to production inputs. In another paper, Ladd and Suvannunt apply the approach to consumer goods. Taking product characteristics as the basic element permits us to do a number of things that we cannot do when we take product as the basic element of analysis. The potentialities of the product characteristics approach to inputs are summarized in the two themes of this paper.

The first theme is that the price of a purchased input equals the sum of the money values of the input's characteristics to the purchaser. The money value of each of the input's characteristics equals the input's marginal yield of the characteristic multiplied by the marginal money value of one unit of the characteristic. The second theme is that the demand for an input is affected by the input's characteristics.

The first section of this paper uses a variant of neoclassical firm theory to derive the two hypotheses stated in the themes and summarizes available statistical studies that bear on these two hypotheses. The next section uses linear programming to derive the hypothesis stated in the first theme and presents results of a study in which linear programming was used to measure the marginal money values of characteristics referred to in the first theme. The subsequent section uses the linear programming results in an evaluation of the present corn-grading system. The next section applies the second theme to the question: What quality of product should a firm produce for maximum profit?

Neoclassical Input Characteristics Model (ICM)

Differences in yields of input characteristics affect producers. A soybean crusher is concerned with the yield of oil and meal per bushel of beans. The amount of nitrogen in a ton of fertilizer makes a difference to a corn producer. This section of the paper presents a variation of neoclassical firm theory that focuses on the role of input characteristics in the production process. This section and the next two are partially a condensation and partially an extension of Martin's thesis.

P1420

Theoretical Model

In this model of a multiproduct firm, each production function is independent of the production functions for other products. The assumption of independence of production functions plays the same role here that the assumption of independence of processes plays in linear programming.

Productive inputs are useful because they contain useful characteristics. The total contribution of an input to production depends upon the amounts of the various characteristics it provides, and total production depends upon the total amounts of all characteristics provided by all inputs. Let v_{ih} = the quantity of the ith input used in the production of the hth product, r_i = the price paid for the ith input, p_h = the price received for product h, q_h = the quantity of the hth output produced, x_{jih} = the amount of characteristic j provided by one unit of input i that enters into production of product h, and $x_{j\cdot h}$ = the total quantity of characteristic j that enters into production of product h. For example, q_h, x_{jih} and $x_{j\cdot h}$ might be amount of choice beef produced, the amount of protein in a bushel of No. 2 yellow corn that is used in production of choice beef, and total amount of protein used in production of choice beef. The values of x_{jih} are assumed to be parameters whose values are beyond the control of the user of the inputs. Write the production function for product h as

$$(1) \qquad q_h = F_h(x_{1\cdot h}, x_{2\cdot h}, \ldots, x_{m\cdot h}).$$

Equation (1) states that the output of the hth product depends upon the amounts of various input characteristics used in its production. The amount of choice beef produced, for example, depends upon the amounts of protein, carbohydrates, calories, vitamin A, etc., fed to the beef. Because total quantity of each characteristic can be expressed as a function of quantities of inputs used and of characteristic input-output coefficients, $x_{j\cdot h}$ can be written as

$$x_{j\cdot h} = X_{jh}(v_{1h}, v_{2h}, \ldots, v_{nh}, x_{j1h}, x_{j2h}, \ldots, x_{jnh}).$$

It follows that the production function can be written as

$$q_h = G_h(v_{1h}, v_{2h}, \ldots, v_{nh}, x_{11h}, x_{12h}, \ldots, x_{mnh}).$$

The firm's profit function can be written as

$$(2) \qquad \pi = \sum_{h=1}^{H} p_h F_h(x_{1\cdot h}, x_{2\cdot h}, \ldots, x_{m\cdot h}) - \sum_{h=1}^{H} \sum_{i=1}^{n} r_i v_{ih}.$$

The firm is assumed to maximize profit.

Because F_h is a function of the $x_{j\cdot h}$ and the $x_{j\cdot h}$ are functions of v_{ih}, to differentiate equation (2) with respect to v_{ih}, we use a rule for differentiating a compound function (a function of functions). According to this rule,

$$\partial F_h/\partial v_{ih} = \sum_j (\partial F_h/\partial x_{j\cdot h})(\partial x_{j\cdot h}/\partial v_{ih}).$$

Using this expression in differentiating equation (2) yields

$$(3) \qquad \partial\pi/\partial v_{ih} = p_h \sum_{j=1}^{m} (\partial F_h/\partial x_{j\cdot h})(\partial x_{j\cdot h}/\partial v_{ih}) - r_i = 0.$$

Solving for r_i,

$$(4) \qquad r_i = p_h \sum_j (\partial F_h/\partial x_{j\cdot h})(\partial x_{j\cdot h}/\partial v_{ih});$$

$\partial x_{j\cdot h}/\partial v_{ih}$ is the marginal yield of characteristic j to production of the hth product from the ith input; $\partial F_h/\partial x_{j\cdot h}$ is the marginal physical product from one unit of characteristic j used in production of the hth product; and $p_h \partial F_h/\partial x_{j\cdot h}$ is the value of the marginal product of the jth characteristic used in production of output h. It can be interpreted as the marginal implicit (or imputed) price paid for the jth product characteristic used in product h. Let $p_h \partial F_h/\partial x_{j\cdot h} = T_{jh}$. Then equation (4) can be written

$$(5) \qquad r_i = \sum_j T_{jh}(\partial x_{j\cdot h}/\partial v_{ih});$$

$T_{jh}\partial x_{j\cdot h}/\partial v_{ih}$ is the value of the marginal yield of the jth characteristic by the ith input in production of output h. Equation (5) states that for each input used in producing output h, the price paid equals the sum of the values of the marginal yields of the input's characteristics to the product. This is the hypothesis stated previously in the first theme.

To obtain the hypothesis stated in the second theme, note that the first-order conditions, equation (3), are a system of nH equations in the nH unknowns v_{ih}. If the second-order conditions for a maximum are satisfied, then the system has a solution, each element of which can be expressed as

$$(6) \qquad v_{ih^*} = V_{ih}(p_1, p_2, \ldots, p_H, r_1, r_2, \ldots, r_n, x_{111}, x_{211}, \ldots, x_{21H}, \ldots, x_{mnH}).$$

In general, it cannot be shown that $\partial v_{th^*}/\partial x_{uvw} = 0$. Thus, we have the second theme.

To look at this in more detail, consider a simple case of a single product firm. Then $h = 1$ and we will suppress the subscript h. From equation (3) we then have n equations of the form

$$(7) \quad \partial\pi/\partial v_i = p\Sigma\partial F/\partial v_i - r_i = 0; \quad i = 1, 2, \ldots, n.$$

Now suppose that the producer of the wth input changes the composition of his product slightly by varying x_{uw} by the amount dx_{uw}. What effect will this change have on the firm's level of use of various inputs? The answer to this question can be expressed in easily understood terms if first the effect of a change in the price of one input on input use is determined. Suppose the price of input g varies. To determine the effect, differentiate the n expressions in equation (7) with respect to r_g and solve for $\partial v_t/\partial r_g$. Define D = symmetric $n \times n$ determinant whose element in row i and column t is $\partial^2 F/\partial v_i \partial v_t$, and D_{it} = cofactor of element in row i and column t of D. The solution for $\partial v_t/\partial r_g$ can be written as $\partial v_t/\partial r_g = D_{gt}/pD$.

The effects of a variation in x_{uw} are found by differentiating equation (7) with respect to x_{uw} and solving for $\partial v_t/\partial x_{uw}$. Let $f_g = \partial F/\partial v_g$ = marginal physical productivity of gth input. Then

$$(8) \quad \partial v_t/\partial x_{uw} = -\sum_g(\partial f_g/\partial x_{uw})(D_{gt}/pD) = -\sum_g(\partial f_g/\partial x_{uw})(\partial v_t/\partial r_g).$$

In the simple case where changing x_{uw} affects only f_u,

$$(9) \quad \partial v_t/\partial x_{uw} = -(\partial f_u/\partial x_{uw})(\partial v_t/\partial r_u).$$

Thus, the effect of a change in the composition of the wth input on demand for the tth input depends upon the effect of the change upon marginal physical productivities of all inputs, and the effect of changes in input prices on demand for the tth input.

We cannot demonstrate on a priori grounds that equation (8) or (9) equals zero. Therefore, equations (6) and (8) provide the hypothesis stated in the second theme.

Empirical Tests

Equation (5) provides the hypothesis: for each input purchased by the firm, the price paid equals the sum of the products of marginal yields of characteristics and marginal implicit prices of characteristics. Testing of this hypothesis is simplified by assuming $\partial x_{j\cdot h}/\partial v_{ih} = x_{jih}$ = constant. This assumption is consistent with the present state of knowledge. Data on product yields of characteristics, e.g., protein per bushel of No. 2 yellow corn, thiamine per pound of round steak, British thermal unit per cubic foot of natural gas, etc., treat yields of characteristics as constants. The data are consistent with an even stronger assumption, namely $x_{jih} = x_{jik}$ for all h and k and all i and j. This states that yield of each characteristic by an input is not affected by the use made of the input: the yield of protein from a bushel of No. 2 yellow corn is the same whether the corn is used to feed hogs or to feed dairy cattle. Assuming $\partial x_{j\cdot h}/\partial v_{ih} = x_{jih}$ = constant and T_{jh} = constant, equation (5) can be written

$$(10) \qquad r_i = \sum_j T_{jh} x_{jih}.$$

Regressing input prices (r_i) upon input characteristics (as measured by x_{jih}) provides a test of the null hypothesis that r_i is not linearly related to the x_{jih}. If the F test for significance of the regression coefficients leads to rejection of the null hypothesis, the data are consistent with the first theme.

If the T_{jh} are not believed constant, one might use

$$(11) \quad r_i = \sum_j x_{jih}\beta_j + \sum_j x^2{}_{jih}\beta_{jj} = \sum_j x_{jih}(\beta_j + x_{jih}\beta_{jj})$$

and determine marginal implicit prices from the terms in parentheses.

Studies by Waugh (1928, 1929), Fettig, Hyslop, and Wachtel and Betsey provide empirical tests of equation (5). All are consistent with the first theme. Waugh found that a substantial portion of the variance in wholesale prices of asparagus, tomatoes, and cucumbers could be explained by characteristics of the vegetables. Waugh collected data on wholesale prices and characteristics of individual lots of asparagus, tomatoes, and cucumbers. He regressed the ratio of the price of each lot to the average price of the product on measures of product characteristics and converted the regression coefficients into prices of product characteristics. For example, from his analysis of prices of asparagus, he concluded that each additional inch of green color per stalk added 38.45¢ to the price of one dozen standard bunches, that each additional stalk per bunch reduced price by 4.6¢,

and that each additional percent variation in size of stalk decreased price by 0.76¢ per dozen standard bunches. For asparagus and tomatoes he used a linear equation, like equation (10). For cucumbers he found a nonlinear relation like equation (11) to be superior to a linear relation.

Fettig found that a large proportion of variance in prices of farm tractors could be explained by horsepower and type of engine. His equation for 1962 prices, for example, was

$$p_i = 288.01 + 53.76H_i + 583.51D_i,\ R^2 = 0.876,$$

where p_i was FOB factory price of ith model of tractor, H_i was horsepower, and $D_i = 1$ if ith model had a diesel engine, and $D_i = 0$ otherwise. Hyslop analyzed prices of hard red spring wheat. He found that a large proportion of the variance in prices could be explained by a linear combination of percentage dockage, protein content, test weight, percentage damaged kernels, percentage of foreign material, percentage of shrunken and broken kernels, area of origin, destination, and transport mode.

Wachtel and Betsey found that an employee's annual wage earnings was linearly related to the employee's years of experience in his present job, race, age, sex, years of education, and marital status. These are the only studies to our knowledge that test the hypothesis of equation (5) and the first theme. Their results are all consistent with the first theme.

Many other studies have found that earnings are related to employee characteristics (see, e.g., Mincer; Johnson and Stafford; Malkiel and Malkiel; Griliches and Mason). But their results cast no light on the hypothesis in equation (5) that price is equal to the sum of the products of marginal yields of characteristics and marginal implicit prices. Their studies used equations of the form $\log r_i = \Sigma T_{jh} x_{jih}$.

We have not found any studies that test the hypothesis of the second theme.

Linear Programming Input Characteristics Model

Theoretical Background

The preceding argument justifies multiple regression as one method for assigning monetary values to characteristics of inputs. That argument applies to any production activity. Application of duality relationships to linear programming blending problems also provides a derivation of the first theme and a method of assigning monetary values to characteristics of inputs used in blending problems, e.g., blending pure metals to produce an alloy, feed mixing. This section discusses appropriate duality relationships. Two different blending problems are treated.

The first is the problem of blending ingredients purchased at fixed prices in order to minimize the ingredient cost of one unit of output. The problem can be stated as

$$\text{(12)} \qquad \min \sum_{j=1}^{n} p_j x_j$$

subject to

$$\text{(13)} \quad \sum_j a_{ij} x_j \geq a_{i0}:\ i = 1, 2, \ldots, m_0,$$

$$\text{(14)} \quad \sum_j a_{ij} x_j = a_{i0}:\ i = m_0 + 1, m_0 + 2, \ldots, m,$$

$$\text{(15)} \quad x_j \geq 0:\ j = 1, 2, \ldots, n_0,$$

and

$$\text{(16)} \quad x_j \text{ unrestricted: } j = n_0 + 1, n_0 + 2, \ldots, n.$$

Here p_j is the price of the jth ingredient; x_j is the quantity of the jth ingredient used per unit of output; a_{ij} is the quantity of the ith nutrient (or other characteristic) in one unit of the jth purchased input; and a_{i0} is the amount of the ith nutrient (or other characteristic) required in one unit of output. The dual to this problem is

$$\text{(17)} \qquad \max \sum_{i=1}^{m} a_{i0} y_i,$$

subject to

$$\text{(18)} \quad \sum_i a_{ij} y_i \leq p_j:\ j = 1, 2, \ldots, n_0,$$

$$\text{(19)} \quad \sum_i a_{ij} y_i = p_j:\ j = n_0 + 1, n_0 + 2, \ldots, n,$$

$$\text{(20)} \quad y_i \geq 0:\ i = 1, 2, \ldots, m_0,$$

and

$$\text{(21)} \quad y_i \text{ unrestricted: } i = m_0 + 1, m_0 + 2, \ldots, m.$$

Equations (13) and (20) state that the first m_0 primal constraints are "greater than or equal to" constraints and the first m_0 dual variables are nonnegative. Equations (14) and (21) state

that the remaining primal constraints are equalities and the remaining dual variables are unrestricted in sign. Equations (15) and (18) state that the first n_0 primal variables are nonnegative and the first n_0 dual constraints are "less than or equal to" constraints. Equations (16) and (19) state that the remaining primal variables are unrestricted and the remaining dual constraints are equalities.[1]

From duality theory, the minimum value of $\Sigma p_j x_j$ equals the maximum value of $\Sigma a_{i0} y_i$; write this as min $\Sigma p_j x_j$ = max $\Sigma a_{i0} y_i$. Now suppose that a_{i0} is changed by the amount Δa_{i0}. Then

$$\Delta\min \Sigma p_j x_j / \Delta a_{i0} = \Delta\max \Sigma a_{i0} y_i / \Delta a_{i0} = y_i,$$

and y_i is interpreted as the shadow price of the ith characteristic. It measures both the effect on minimum total ingredient cost per unit of output of varying a_{i0} and also the effect on maximum monetary value of nutritional (or other characteristic) requirements of varying a_{i0}. Then each constraint in equation (19) states: the total money value of all characteristics in one unit of input j (for $j = n_0 + 1, n_0 + 2, \ldots, n$) equals the price of ingredient j. (This is an exact counterpart to equation (5).) Letting x_{j*} and y_{i*} denote optimal values of primal and dual variables, a duality theorem tells us that if $x_{j*} > 0$ in the optimal solution to equation (12), then $\Sigma a_{ij} y_{i*} = p_j$. This expression is also an exact counterpart to equation (5). Hence, linear programming provides a derivation of the first theme.

The second blending problem concerns a firm that has a number of bins of corn, and the characteristics of each bin are known. Hence, the firm knows how many pounds of corn, of damaged kernels, etc., it has in each bin and in total. Let r_i = total stock of the ith characteristic (e.g., number of pounds of corn or of damaged kernels), x_j = quantity of jth output blended and sold, c_j = net revenue (selling price minus per unit blending cost) of jth output, and a_{ij} = amount of ith characteristic required per unit of jth output. This firm's profit-maximizing blending problem is

$$(22) \qquad \max \sum_j c_j x_j,$$

subject to

$$\sum_j a_{ij} x_j \leq r_i: i = 1, 2, \ldots, m_0,$$
$$\sum_j a_{ij} x_j \geq r_i: i = m_0 + 1, m_0 + 2, \ldots, m_1,$$
$$\sum_j a_{ij} x_j = r_i: i = m_1 + 1, m_1 + 2, \ldots, m,$$
$$x_j \geq 0: j = 1, 2, \ldots, n_0,$$

and

$$x_j \text{ unrestricted}: j = n_0 + 1, n_0 + 2, \ldots, n.$$

The dual to this problem is

$$(23) \qquad \min \sum_i r_i y_i$$

subject to

$$\sum_i a_{ij} y_i \geq c_j: j = 1, 2, \ldots, n_0,$$
$$\sum_i a_{ij} y_i = c_j: j = n_0 + 1, n_0 + 2, \ldots, n,$$
$$y_i \geq 0: i = 1, 2, \ldots, m_0,$$
$$y_i \leq 0: i = m_0 + 1, m_0 + 2, \ldots, m_1,$$

and

$$y_i \text{ unrestricted}: i = m_1 + 1, m_1 + 2, \ldots, m;$$

$\Delta\max \Sigma c_j x_j / \Delta r_i = \Delta\min \Sigma r_i y_i / \Delta r_i = y_i$; y_i is the shadow price of the ith characteristic. It is the maximum amount the firm can afford to pay for one more unit of the ith characteristic; it is also the reduction in net revenue resulting from reducing the firm's stock of the ith characteristic by one unit.

Assume the firm considers buying one bushel of corn at price p. Let Δr_i be the amount of the ith characteristic in the bushel of corn. Then the resulting change in the firm's net revenue is

$$(24) \quad \Delta\max \Sigma c_j x_j = \sum_i (\Delta\max \Sigma c_j x_j / \Delta r_i) \Delta r_i = \sum_i y_i \Delta r_i.$$

The firm can afford to buy and use the bushel of corn if

$$(25) \qquad \Sigma y_i \Delta r_i \geq p.$$

Equation (25) is an inequality variant of the first theme; $\Sigma y_i \Delta r_i$ is the maximum price the firm can afford to pay for the bushel of corn having the specified characteristics.

Some Empirical Results for Corn

The linear program, equation (22), was used to determine the optimum use of four carloads of corn actually shipped from a central Iowa elevator in the fall of 1971. The values of r_i

[1] The authors are aware that few blending problems contain unrestricted variables. Suppose that the first restriction is $\sum_j a_{1j} x_j \leq a_{10}$. Multiplying both sides of this constraint by -1 reverses the sense of the inequality and the resulting restriction has the same form as equation (13). Then equation (20) becomes $y_1 \leq 0$; $y_i \geq$ for $i = 2, \ldots, m_0$.

Table 1. Linear Programming Corn-Blending Problem 11

Characteristic i	Values of a_{ij}: $j = 1$[a]	$j = 2$	$j = 3$	$j = 4$	$j = 5$	Form of Constraint	r_i
$i = 1$: moisture	0.140	0.155	0.175	0.200	0.230	≥	1,851 bu.
$i = 2$: test weight	56.000	54.000	52.000	49.000	46.000	≤	675,024 lb.
$i = 3$: BCFM	0.020	0.030	0.040	0.050	0.070	≥	560 bu.
$i = 4$: damaged kernels	0.030	0.050	0.070	0.100	0.150	≥	168 bu.
$i = 5$: weight	56.000	56.000	56.000	56.000	56.000	=	672,000 lb.
c_j: \$/bu.	1.00	1.00	0.91	0.79	0.63		

[a] Value of j identifies grade of corn produced by blending and sold.

measured the amounts of moisture, test weight, broken corn and foreign material (BCFM), damaged kernels, and actual weight of the four carloads of corn. Five products could be obtained by blending this corn: United States No. 1, 2, 3, 4, and 5 corn. The amount of ith characteristic required per bushel of the jth grade of corn = a_{ij}. For moisture, BCFM and damaged kernels, a_{ij}, equals the official U.S. specification for the maximum amount of the ith characteristic allowed per bushel of the jth grade of corn. For test weight, a_{ij} equals the minimum official test weight per bushel of jth grade of corn. Eleven problems were obtained by varying BCFM in fifty-six bushel increments above and below its actual value. Problem 11 is shown in table 1.

The interest here is not in the amounts of various products to blend and sell, as it usually is in blending problems. In accordance with the first theme, the interest is in the implicit (shadow) prices of the various characteristics. Table 2 summarizes the values of the shadow prices from the optimal solutions to the 11 blending problems; these shadow prices are the y_i in problem (23).

In the solution to problem 11, for example, the shadow price for weight is 2.29¢ per pound. A firm whose stocks of corn were as described in the last column of table 1 could have increased its net revenue (sales revenue minus blending costs) by 2.29¢ if it had owned one more pound of corn. This means that the firm could have afforded to pay 2.29¢ for a pound of corn; it also means that the firm's net revenue would have been 2.29¢ less if it had owned one less pound of corn. Variations in the firm's stocks of moisture, test weight, or damaged kernels would not have affected the firm's net revenue.

Table 2 shows that weight had a positive shadow price in each solution. BCFM had a zero shadow price in each of the first five

Table 2. Shadow Prices for Linear Programming Corn-Blending Problems 1 through 11

Characteristic	Imputed (shadow) Prices[a]
Solutions 1 through 5: BCFM = 0; 56; 112; 168; 224 bu.	
Moisture	0
Test weight	0
BCFM	0
Damage	0
Weight	1.78
Solutions 6 and 7: BCFM = 280; 336 bu.

Damage	0
Weight	2.29

[a] Cents per bushel for moisture, BCFM and damaged kernels; cents per pound for test weight and weight.

solutions and had a negative shadow price in each of the last six solutions. Shadow prices for all other characteristics were zero in all solutions.

These four carloads of corn happened to grade fairly high. Another solution—No. 12—was obtained in which the r_i for test weight was reduced by 5.5% and the r_i for BCFM was set at 129 bushels while other values of r_i remained unchanged. In the solution to this problem, damaged kernels had a shadow price of $50 per bushel.

Another blending linear program—No. 13—was run for a firm producing thirteen different products: No. 1 through No. 5 corn; two mixed feeds; and corn for storage, dry millers, distillers, exporters, wet millers, and food processors.[2] In addition to corn, the firm used oats and soybean oil meal. The only corn characteristic having a nonzero shadow price in the optimal solution was corn weight. Its shadow price was 9.5¢ per pound, which is much larger than the shadow prices for weight in table 2.

The next section applies these results to evaluation of corn grades.

Application of ICM to Corn Grades

Two questions must be considered in establishing or evaluating a grading system. What characteristics of the product should be included? How should the information be reported? Included under this second question is the question: How should the information be condensed for reporting? Should it be condensed into a numerical grade using the lowest-quality-characteristic method now used for corn? (Suppose a lot of corn meets the requirements for No. 1 corn on two characteristics, for No. 2 corn on two others, and for No. 3 corn on a fifth characteristic. That lot of corn then is graded No. 3, based on the lowest-quality characteristic.) Should it be condensed into a composite (numerical) grade as described by Hyslop? Marginal implicit prices of characteristics can be used in determining answers to both questions. The following discussion focuses on the reporting issue, but many of the points presented also have implications for the first question.[3]

[2] The specifications for these last products were averages obtained from surveys of corn processors.

[3] This is not intended to be a thorough evaluation of corn grades but is only intended to illustrate how ICM may be used to evaluate grades and standards. More details are available in Martin.

Given a list of characteristics, let us say that a grading system is sign-optimal for a given firm with respect to that list (*a*) if the list of grading characteristics having positive marginal implicit prices for the firm is the same as the list of characteristics that raise grade (e.g., No. 3 to No. 1) when their yield per bushel rises; (*b*) if the list of grading characteristics having negative marginal implicit prices for the firm is exactly the same as the list of characteristics that lower grade (e.g., No. 1 to No. 2) when their yields per bushel rise; and (*c*) if the list of characteristics having zero marginal implicit prices is the same as the list of characteristics whose variations have no effect on grade. These three conditions can be summarized in one condition: for every characteristic, varying the yield per bushel of the characteristic has the same effect on grade as on per unit value of the commodity to the firm.

From the standpoint of the individual firm, sign-optimality certainly is a desirable characteristic. (Strictly speaking, no numerical grading system can be sign-optimal for any firm because of the ranges allowed in each grade.) The linear programming results presented earlier suggest serious problems in attaining sign-optimality. The present corn grading system is not sign-optimal for a firm that finds itself in any one of the situations analyzed in the thirteen different problems. For example, marginal implicit prices for moisture are zero in every solution, yet variations in moisture content affect grade. This violates property (*c*). Further, it is not possible to find a subset of the characteristics currently used in grading corn that provide a sign-optimal numerical grading system for all of these thirteen situations.

Knapp made a linear programming study of the corn-blending and merchandising operations of an Iowa regional grain marketing cooperative. For each of some 190 bins of corn, he determined per bushel net marginal value product (NMVP) as the excess of per bushel MVP over the market price of corn having the same characteristics as the corn in the bin. Adding to each NMVP the price of corn having the same characteristics as the corn in the bin yields the MVP for the corn in the bin. Ranges in values of MVPs are shown in table 3. MVP equals $\Sigma y_i \Delta r_i$ as defined in equation (24).

A grading system that was sign-optimal would not yield results like these. Under a

Table 3. Ranges in Values of MVPs for Bins of Different Grades of Corn

Grade	MPV range, $/bu.
1	1.0785 to 1.0978
2	1.040 to 1.1267
3	1.0215 to 1.0993
4	1.0015 to 1.0874
5	1.0000 to 1.07852
Sample	1.02074 to 1.08815

Source: Knapp.

sign-optimal system, the highest MVP for one grade of corn would be less than the lowest MVP for the next better grade of corn. In this table, the highest MVP for sample grade corn (the lowest grade) exceeds the lowest MVP for every one of the higher grades of corn, and the highest MVP for sample grade corn exceeds the highest MVP for No. 4 grade corn. The firm could afford to pay a higher price for some sample grade corn than for some corn of grades 1, 2, 3, 4, and 5. The highest MVP for No. 3 grade corn exceeds the lowest MVPs for No. 1 grade corn (the highest grade) and No. 2 corn. The firm could afford to pay more for some No. 3 corn than for some No. 1 and No. 2 corn. In summary, the firm could afford to pay more for some lots of corn of one grade than for some lots of corn of a higher grade.

These linear programming solutions support the hypothesis that it is impossible to develop a numerical grading system that will be sign-optimal for a substantial number of firms. Additional evidence to support this hypothesis is presented by Martin. One hundred ninety-seven country elevators and ninety-one firms in five different corn-using industries were asked to rank each of nine characteristics of corn in order of importance to itself. The ranks varied substantially among industries and also within industries, as shown in tables 4 and 5. For the firms in each industry, a pooled (or average) rank was computed for each characteristic. Table 4 shows substantial variation in the relative importance of many of the characteristics. Total damage, for example, varies from second in importance for country elevators to sixth in importance for dry millers. Moisture varies from second in importance for exporters and feed manufacturers to eighth for wet millers.

Substantial variation also existed among firms in the same industry. To measure the extent of agreement among the ranks assigned by two firms in the same industry, one can use a coefficient of rank correlation. To measure the extent of agreement among the ranks assigned by several firms, Kendall's coefficient of concordance, W, can be used. Its value ranges from zero, indicating no agreement or independence of the rankings, to one, indicating perfect agreement among the rankings. A coefficient of concordance was computed for the firms in each corn-buying industry. The values of W are presented in table 5. Each value of W is significant at the 1% level; the hypothesis of independence of rankings is therefore rejected for each industry. However, substantial disagreement existed within each industry as evidenced by the difference of each value of W from one.

The difficulty in attaining sign-optimality for all firms comes from, among other things, variations over time and among firms in input and output prices, stocks, technologies used, and the characteristics of the final products. Sign-optimality is a rather modest requirement for a

Table 4. Pooled Ranks of Importance of Corn Characteristics

Characteristic	Country Elevator	U.S. Exporter	Wet Miller	Dry Miller	Distiller	Feed Manufacturer

grading system; yet our results show the present corn-grading system cannot achieve it, nor can any other system of numerical grades achieve it.

We suggest an alternative to numerical grades for reporting the information now obtained in grading corn: the specified-order method of reporting. This method comes closer to achieving sign-optimality than any system of numerical grades.

Suppose we have a carload of corn in which (*a*) test weight per bushel is 55.0 pounds, (*b*) moisture content is 16.2%, (*c*) BCFM is 2.5%, (*d*) total damaged kernels are 4.1%, and (*e*) heat-damaged kernels are 0.1%. According to current U.S. corn standards, this grades No. 3. Yet the corn is No. 2 on characteristics (*a*), (*c*) and (*d*), and No. 1 on characteristic (*e*). The specified-order method of describing this corn would not report that this is No. 3 corn. It would list the numerical values of all five characteristics in some specified order. Suppose the specified order were the order listed in (*a*) through (*e*). Then this would be described as a carload of "55.0-16.2-2.5-4.1-0.1 corn." Basically, this is a nongrading method because no grade is assigned by an official grader. The official "grader" would make the same tests that he does now. But instead of condensing these five numbers into one numerical grade, he would simply report all five numbers in a specified order.

The specified-order method could be used with one base specification being used for purposes of price reporting and futures trading. Present specifications for U.S. No. 2 corn for test weight (54 pounds), broken corn and foreign material (3%), and total damaged kernels (5%), and the moisture specification for U.S. No. 1 (14%) would be the most acceptable base grade, according to the responses to corn industry questionnaires.

Although the specified-order method would abolish numerical grades, grain dealers could continue to blend to specifications. The base grade probably would become the typical blending specification, but other characteristic specifications could be requested by buyers. Because the base grade is suitable for storage and almost all uses, premiums probably would not be paid for corn exceeding the base specifications. Buyers would have the option of using flexible discounts for lots not meeting the base grade. Implicit characteristic prices derived from linear programming models could be used to determine discount schedules for characteristics, although custom and competition probably would limit the frequency of changing the discount schedules.

We will not go into the question of selecting the characteristics to be included in a grading system except to note this. The second paragraph of this section listed three properties of a sign-optimal grading system. The last one was: the characteristics having zero marginal implicit prices have no effect on grade. This property could be used to determine which characteristics to exclude from a grading system: those characteristics having zero (or small) marginal implicit prices for a large number of firms under a variety of market conditions.

Application of ICM to Product Line Selection

Consider a competitive firm producing goods that are inputs to other firms, e.g., a cattle feeder selling to a packer. Because the firm is in a competitive industry, it cannot affect the price it receives by varying the amount it produces. It can, however, affect the price it receives by varying the "quality" of its output. What quality of product should it produce for maximum profit? Let us measure quality by the amounts of various characteristics contained in one unit of product. Define p and q as price and quantity of product; define x_i as the amount of the ith characteristic in one unit of product; define $c(q, x_1, x_2, \ldots, x_n)$ as the average cost function; and define $p(x_1, x_2, \ldots, x_n)$ as the function relating quality to price. Then the firm's profit is

$$\pi = qp(x_1, x_2, \ldots, x_n) - qc(q, x_1, x_2, \ldots, x_n).$$

One first-order condition for profit maximization is the familiar "price equals marginal cost" condition:

$$\partial \pi / \partial q = p - (q \partial c / \partial q + c) = 0.$$

To determine the profit-maximizing level of x_i,

$$\partial \pi / \partial x_i = q \partial p / \partial x_i - q \partial c / \partial x_i = 0.$$

If $q \neq 0$, it follows that

$$\partial p / \partial x_i = \partial c / \partial x_i.$$

The equilibrium level of x_i is achieved when the marginal effect of x_i on price equals the marginal effect of x_i on average production cost.

Summary and Limitations

The model presented here is not a theory of prices; a theory of prices deals with the supply side as well as the demand side of the market. But ICM deals only with demand for input characteristics and not with supply of input characteristics. The model presented here complements existing theories. Suppose, for example, an unfortunate combination of floods and droughts drastically reduces the corn crop. Existing theory tells us how the resulting shift in supply of corn affects prices of corn. Equation (5) simply states that the price (whatever it may have been) of a grade of corn before the shift in supply exactly equalled the total marginal monetary values of the characteristics of the corn for each firm who purchased it. And it states that the same equality prevails for the price (whatever it may be) after the shift in corn supply. Equation (5) and the linear programming model suggest how the marginal implicit prices can be estimated both before and after the shift in corn supply.

In their statistical studies, Hyslop and Waugh (1928, 1929) obtained some negative implicit prices. Negative implicit prices are consistent with ICM and with observation. Some product characteristics may be "inferior characteristics," that is, their presence in any amount reduces the value of a product. Other characteristics may have positive marginal prices up to a point but negative marginal prices after that point. Increasing the length of a truck may increase the value of the truck up to some point because it provides more cargo room. But beyond that point, additional length may reduce the value of the truck because it makes it too long to fit into one's garage, too long to negotiate street corners, and dangerous to drive.

Impact of Socioeconomic Factors on Consumption of Selected Food Nutrients in the United States

John Adrian and Raymond Daniel

The impacts of socioeconomic characteristics of the household and its constituents on consumption of protein, carbohydrate, fat, vitamin A, calcium, iron, thiamine, and vitamin C were estimated. Data from 6,950 households located in the contiguous states were utilized to specify consumption relationships. Socioeconomic factors considered were: income, degree of urbanization, race, educational attainment of the homemaker, stage of the household in the family life cycle, family size, meal adjustment, and employment status of the homemaker. Income had a positive impact on the consumption of all nutrients except carbohydrate. However, nutrient consumption responsiveness to income was relatively small.

Key words: consumption, food nutrients, households, income, United States.

A greater awareness of "consumerism" and increased public interest in nutritional levels has heightened the need for a more complete understanding of nutrient consumption patterns. Despite the availability of a plentiful and varied food supply at relatively acceptable prices, nutrient consumption levels may not be sufficient. Unequal distribution of economic and other resources, differences in sociological factors, and the diversity and complexity of channels used to purchase food have resulted in variations in the consumption of food nutrients by households.

Food consumption research has focused on specifying the relationship between selected socioeconomic factors and the traditional quantity and expenditure measures (Burk 1961, 1968; George and King; Price; Thomas). However, these two approaches limit inference relative to the nutritional status of household diets, that is, a large quantity of food or a large expenditure for food may not generate acceptable levels of nutrient consumption. Therefore, specification of the impact of various socioeconomic characteristics of the household on nutrient consumption could provide insight relative to nutrient consumption patterns of households in the United States. For instance, the relationship between income distribution and nutrient consumption by American households can be evaluated, and knowledge of these relationships can be utilized to develop nutrition education programs by focusing attention on households with low levels of nutrient consumption. Since certain commodities or commodity groups are primary sources of specific nutrients, specification of these relationships can also provide information concerning future demand trends which will directly affect the types of agricultural products produced and marketed in the United States.

Several studies have focused on specifying the influence of household income and other socioeconomic characteristics on nutrient consumption, but most of these have been limited to localized areas or particular groups of people (Babcock; Einstein and Horstein; Kelsay; Madden and Yoder). Generally, these studies noted significant variations in nutrient consumption with respect to income, education, and race. National and regional studies conducted primarily by the U.S. Department of Agriculture have involved only tabular analyses. The purpose of this paper is to analyze estimates of the effects of selected characteristics of the household and its constituents on food nutrient consumption in the United States.

John Adrian is an assistant professor of agricultural economics at Auburn University and Raymond Daniel is director of agricultural economics with Chase Econometric Associates.

This paper is based on research conducted under Objective C of the Southern Régional Demand Project, Demand For Food (SM-45), in the Department of Agricultural Economics and Rural Sociology at the University of Tennessee.

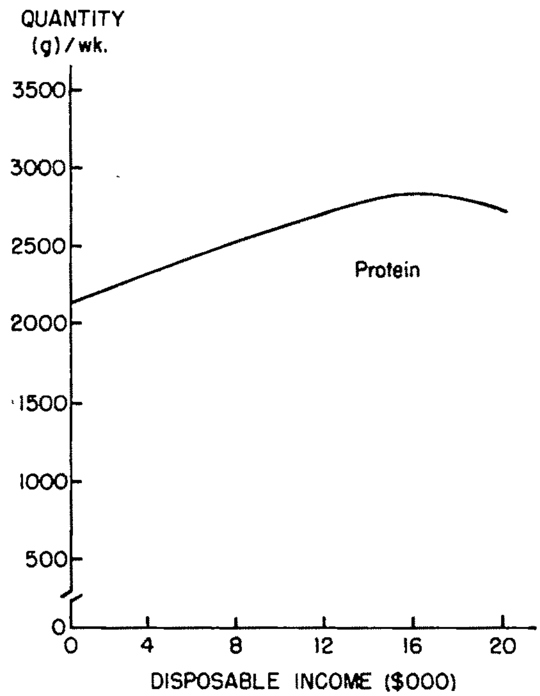

Figure 1. Protein income-consumption relationship

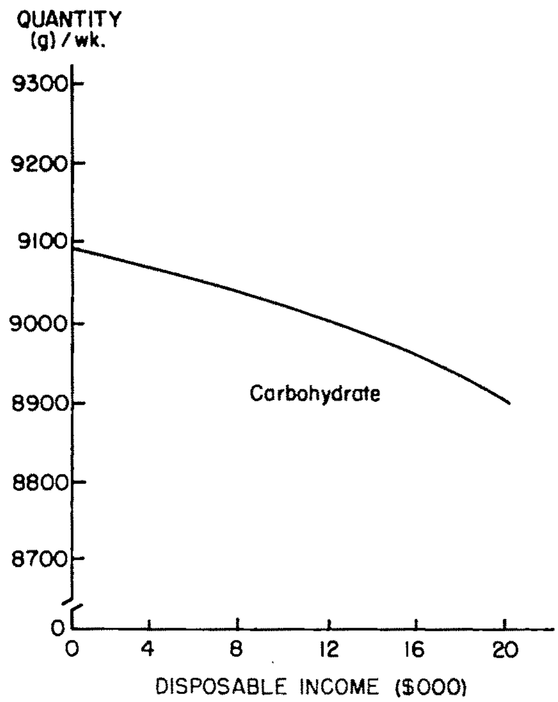

Figure 2. Carbohydrate income-consumption relationship

Data and Model

Data from the 1965–66 nationwide household food consumption survey conducted by the Consumer and Food Economics Research Division, USDA are utilized. The original USDA survey included approximately 7,500 households located in the contiguous states. This analysis includes data from usable schedules for 6,950 households.[1]

The quantities of the respective nutrients consumed per household are computed by multiplying the quantity of each food consumed by the household times the percent of each nutrient available in each unit of food. The summation of this product over all foods for each respective nutrient provides an approximation of the quantity of each nutrient available for consumption by the household per week.[2] Nutrients included in this analysis are protein, carbohydrate, fat, vitamin A, calcium, iron, thiamine (vitamin B_1), and vitamin C.[3]

The economic and sociological characteristics of the household hypothesized to influence consumption of these nutrients are income, degree of urbanization, race, educational attainment of the homemaker, stage of the household in the family life cycle, family size, meal adjustment, and employment status of the homemaker.

Multiple regression analysis is used to estimate the following relationships for households in the United States.[4] The statistical model utilized is

$$\begin{aligned} Q_i = a &+ b_1Y + b_2Y^2 + b_3U_1 + b_4U_2 \\ &+ b_5R_1 + b_6R_2 + b_7E_1 + b_8E_2 + b_9E_3 \\ &+ b_{10}L_1 + b_{11}L_2 + b_{12}L_3 + b_{13}L_4 \\ &+ b_{14}L_5 + b_{15}S + b_{16}M + b_{17}F + u, \end{aligned}$$

where Q_i = quantity of the ith nutrient ($i = 1, \ldots, 8$) consumed per household per week, that is, Q_1–Q_3 = grams of protein, carbohydrate, and fat; Q_4 = international units of vitamin A; and Q_5–Q_8 = milligrams of calcium, iron, thiamine, and vitamin C; Y = an-

[1] The 550 households were eliminated from the analysis because relevant income, race, and other data were missing.

[2] The quantity of food and nutrients consumed by the household represents total quantity available for consumption and not necessarily the quantities eaten by household members. Some food was discarded in the kitchen and at the table. Nutrient supplements (vitamins, etc.) were not included in the survey so some households could have consumed larger quantities of some nutrients. Average nutritional content of the various foods was adjusted for loss of nutrients during preparation (USDA 1969, pp. 1–4).

[3] Estimates for animal protein, vegetable protein, food energy, riboflavin, and niacin were also made (Adrian).

[4] The same model was estimated for the four major regions of the United States. The results of these models deviated little from the aggregate model (Adrian).

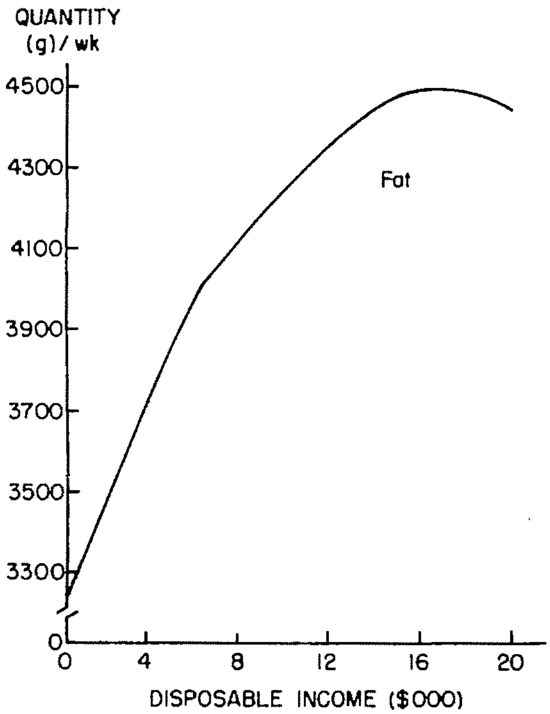

Figure 3. Fat income-consumption relationship

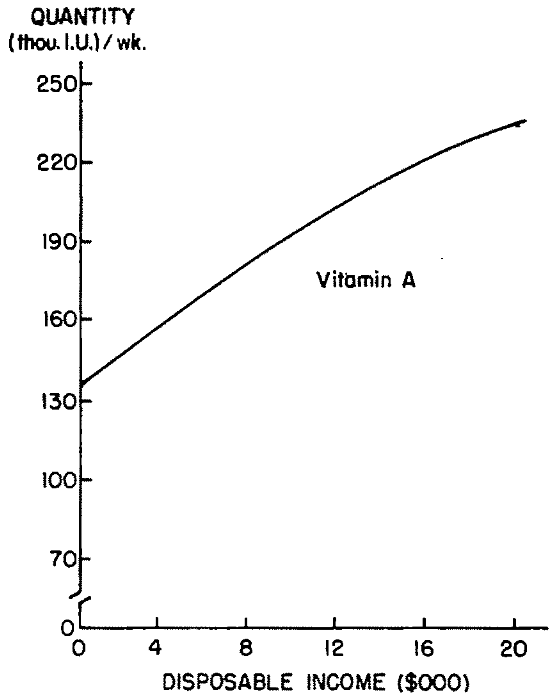

Figure 4. Vitamin A income-consumption relationship

nual household disposable income, $1,000;[5] U_0–U_2 = degree of urbanization (rural farm, urban, and rural nonfarm); R_0–R_2 = race of the household (black, white, and other); E_0–E_3 = educational attainment of the homemaker (high school, grade school, some college, and college graduate); L_0–L_5 = stage of the household in the family life cycle: average age of the children is between six and twelve years—stage 3; no children are present and the housewife is forty years of age or less—stage 1; average age of the children is less than six years—stage 2; average age of the children is between twelve and seventeen years—stage 4; average age of the children is over seventeen years—stage 5; and no children are present and the housewife is over forty years of age—stage 6 (consult Lansing and Kish for a more detailed explanation of this variable); S = family size which is the total number of individuals in a household who depend on a common pool of income for their livelihood; M = meal adjustment which represents the influence of home, guest, skipped, and away meals (meal adjustment is computed as the difference between the number of meals each household reported serving and the number of family members multiplied by 21; the 21 represents meal equivalents per week for one household member); and F = employment status of the homemaker (employed and unemployed).[6]

The same socioeconomic behavioral model is used for each nutrient because nutrients are constituent parts of food; therefore, the same factors may affect the consumption of each nutrient.[7] Each nutrient may be affected differently by the various factors, but there are no a priori justifiable reasons to include or delete a variable for any one nutrient estimate.

Consumers purchase the respective nutrients through their allocation of income to various food products. In making this allocation, consumers are assumed to be making decisions which reflect their desire to have and maintain a balanced and adequate diet. This

[5] The income for households was classified in the original data into fourteen classes, ranging from under $1,000 to $25,000 and over. The middle of each range was used as the actual observation for each family within that range except for the $25,000 or more class where $25,000 was used. See Lee and Phillips for an example of using this approach in estimating Engel curves.

[6] Zero-one dummy variables are utilized to analyze the impact of urbanization, race, educational attainment, family life cycle, and employment status of the homemaker. The initial class in each category, as indicated, is excluded to avoid singularity.

[7] Rather than scale the dependent variables to account for variations in household size and composition implicitly, these factors are entered as independent variables in the models and their impacts are estimated explicitly. Multicollinearity was not encountered.

assumption is not without exception because some of the food consumed by individuals is based on nonnutritive criteria such as habit or impulse consumption. Nevertheless, consumers must make some effort to consume at least minimal quantities of the basic nutrients for the sustenance of life. On the other hand, nutrient consumption is limited by the food consumption capacity of members of the household and also, the desire or necessity of purchasing other goods and services. Thus, the ratio of the quantity of the nutrient consumed to disposable income would not be constant at each subsequent level of income, i.e., a curvilinear relationship is expected. Therefore, a quadratic functional form is utilized to estimate the respective nutrient consumption relationships.[8]

Results

The models postulated to explain variations in household nutrient consumption are acceptable considering the use of cross-section data. Variations in the independent variables included in the models explain more than 50% of the variation in household consumption of protein, carbohydrate, fat, calcium, iron, and thiamine (tables 1 and 2). Similarly, these variables explain 18% and 30% of the variation in household consumption of vitamins A and C, respectively.

Income

Annual household disposable income is a significant factor affecting household consumption of protein, fat, vitamin A, calcium, iron, thiamine, and vitamin C (tables 1 and 2). Consumption of all of these nutrients except calcium and thiamine increases initially, peaks, and declines with successive positive increments of income as is indicated by the significant positive and negative signs of the income and income-squared coefficients. In the models for calcium and thiamine consumption, income coefficients are positive and significant, but the income-squared coefficients have relatively large standard errors. Standard errors in the carbohydrate equation are larger than the estimated income coefficients.

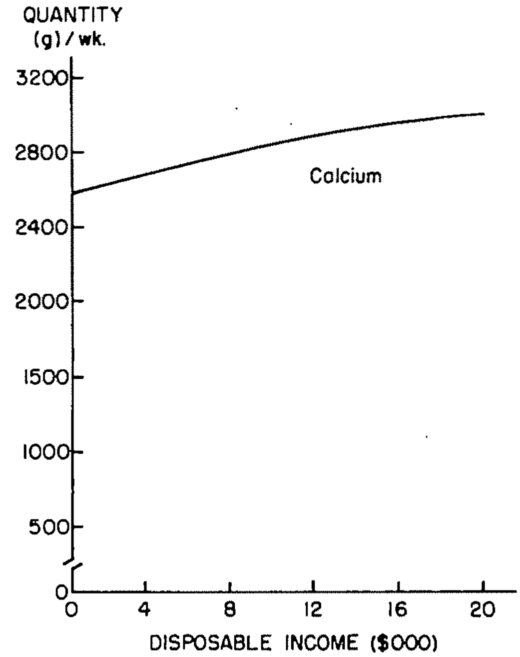

Figure 5. Calcium income-consumption relationship

The relationship between disposable income and consumption of the respective nutrients is further illuminated by the income-consumption relationships illustrated in figures 1–8. These estimates were derived from the respective food nutrient consumption estimates by shifting income from level to level and holding socioeconomic variables other than income at their means.

Nutrient consumption is not highly responsive to income changes as is indicated by the relatively small elasticities in table 3.[9] However, the elasticities do indicate positive responsiveness at all selected income levels for fat, vitamin A, calcium, and vitamin C. Similarly, positive consumption responses are noted for protein, iron, and thiamine consumption at all selected income levels except $20,000 where the response is negative. Over the income spectrum considered, the largest responses occur for protein, fat, iron, thiamine, and vitamin C at the $8,000 level and for vitamin A and calcium at the $12,000 level.

[8] Several alternative functional forms were utilized to determine the functional relationship between income and household consumption of the respective nutrients. The functional forms evaluated, *ex post*, were: linear, semilogarithmic, double-logarithmic, cubic, and transcendental. Based on the coefficients of determination (R^2's) and statistical significance of income coefficients for these functional forms, the quadratic form appeared to be the most appropriate for all nutrients.

[9] Inherent in the analysis of income elasticities for cross-section data is the assumption that a household at one income level will consume as much of a certain nutrient as does a household at a different income level if its income is increased to the new level.

Table 1. Consumption Relationships for Protein, Carbohydrate, Fat, and Vitamin A, Spring 1965–66

Variable	Protein (g.)	Carbohydrate (g.)	Fat (g.)	Vitamin A (I.U.)

Other Variables

Degree of urbanization may reflect the composite impact of such factors as the potential for home food production, accessibility to diverse types of stores including food stores providing a wide variety of foods, distinctions in the social, cultural, and economic environment such as occupational and educational opportunities, and the effects of mass media. The results indicate that farm households consume more of all nutrients except vitamins A and C than do urban or rural nonfarm households (tables 1 and 2). Vitamin A consumption is greater for rural farm than for rural nonfarm families. Vitamin C consumption does not vary significantly by degree of urbanization of the household.

The results suggest that nutrient consumption differs by race of the household (tables 1 and 2). Black households consume less carbohydrate, calcium, and thiamine than do either white or other race households. Also, black households consume less vitamin C, iron, and thiamine and more fat than do other race households. Similarly, they consume more protein and less vitamin A than do white households.

An inverse relationship is noted between educational attainment of the housewife and carbohydrate, fat, iron, and thiamine consumption (tables 1 and 2). Conversely, vita-

Table 3. Nutrient Income Elasticities

	Selected Income Levels					
Nutrient[a]	$2,000	$4,000	$8,000	$12,000	$16,000	$20,000
Protein	0.059	0.098	0.126	0.103	0.034	−0.084
Fat	0.066	0.109	0.142	0.119	0.049	0.072
Vitamin A	0.067	0.115	0.172	0.188	0.173	0.130
Calcium	0.019	0.034	0.050	0.051	0.037	0.009
Iron	0.027	0.046	0.065	0.059	0.031	−0.020
Thiamine	0.016	0.028	0.038	0.032	0.012	−0.024
Vitamin C	0.148	0.233	0.299	0.283	0.208	0.078

Note: Elasticities are affected by the functional form selected to derive estimators of the coefficients. These elasticities were computed from a quadratic function with all factors except income held at mean values and the quantity of the respective nutrient consumed allowed to vary only in response to changes in disposable income.

[a] Elasticities for carbohydrate are excluded because the relationship between income and quantity consumed was not significant at the 0.05 level.

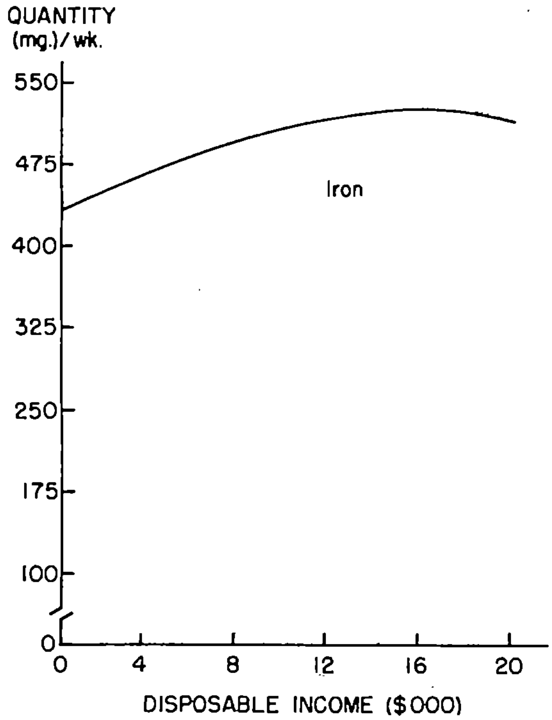

Figure 6. Iron income-consumption relationship

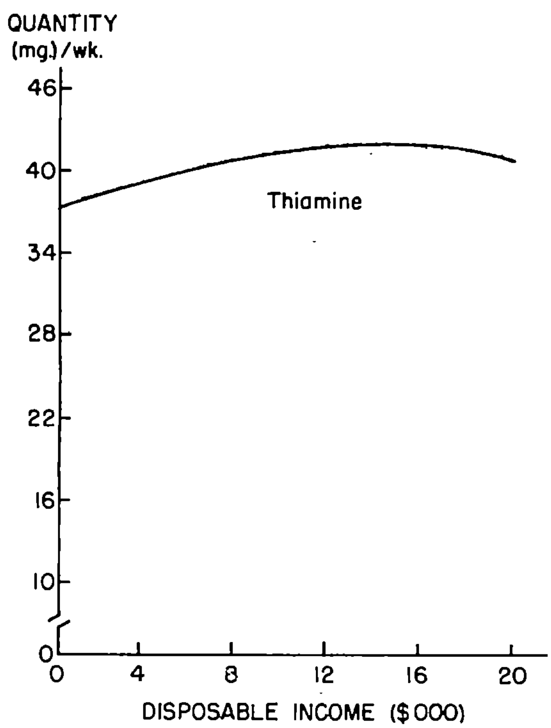

Figure 7. Thiamine income-consumption relationship

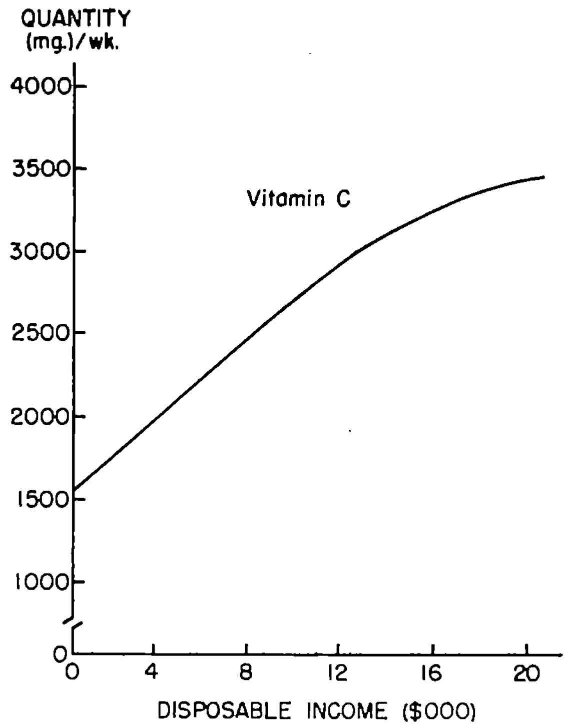

Figure 8. Vitamin C income-consumption relationship

min C consumption tends to increase with additional formal education of the housewife. Similar tendencies are not present for protein, calcium, or vitamin A consumption.

The age of the housewife and the presence and average age of the children in the household, as represented by the family life cycle variable, influence food nutrient consumption (tables 1 and 2). The results suggest that households with children under six years of age (stage 2) and households without children and with the housewife over forty years of age (stage 6) consume smaller quantities of all nutrients than do households with the average age of the children between six and twelve years (stage 3). Households with no children and a housewife under forty years of age (stage 1) consume less of all nutrients except carbohydrate, iron, and thiamine than do base households (stage 3). Households with children from twelve to seventeen years (stage 4) consume the largest quantities of all nutrients except vitamin A.

Family size and meal adjustment affect consumption of the respective nutrients positively, as was expected (table 1 and 2). Thus, an increase in family size is associated with an increase in nutrient consumption. Also, an in-

crease in either home or guest meals increases nutrient consumption, while an increase in either skipped or away from home meals has the opposite effect.

Consumption of carbohydrate and fat is greater for households with an employed housewife (tables 1 and 2). Other differences in nutrient consumption between households with employed and unemployed housewives are not significant.

Summary and Conclusions

Several characteristics of the household and its constituents influence household consumption of food nutrients. Income is a significant positive factor affecting the consumption of all nutrients except carbohydrate. Increases in consumption, however, are not proportional to increases in disposable income. Nutrient consumption responsiveness to income is relatively small with the greatest responsiveness noted in the \$8,000 to \$12,000 income range. This implies that future income increases (in real terms) above this range will have a smaller impact on food consumption in the United States.

The positive income elasticities add credence to policy aimed at generating nutritionally adequate diets through income transfers, but their relatively small magnitudes indicate that nutrient consumption is not highly responsive to income. Therefore, if the primary goal of the policy is to alleviate nutritional deficiency, direct food transfers may be more effective than income transfers.

An analysis of the impact of other socioeconomic factors reveals some significant differences in consumption of the various food nutrients. Urban and rural nonfarm households consume smaller quantities of all nutrients except vitamins A and C than do farm households. Thus, a continued trend toward a more urban society in the United States will result in a possible relative decline in consumption of all nutrients except vitamins A and C. This occurrence is most likely the result of decreased home food production by families in urban areas and decreased food consumption because of more sedentary work habits. Similarly, black households consume less carbohydrate, calcium, and thiamine than do either white or other race households. Also, the more educated housewives seem to serve meals to their families with less carbohydrates and fats and more vitamin C. Finally, households with employed housewives consume more carbohydrates and fats. These results indicate that food nutrition programs could possibly be more effective if directed toward urban, less educated, black households.

Analyzing Hog Production Strategies with a Simulation Model

Malcolm J. Blackie and J. Barry Dent

Simulation modelling has attracted considerable farm management research interest in recent years, yet the on-farm use of simulation models has been limited. A simulation model for hog production has been developed as part of an information system which may assist hog farm managers both in choosing between competing management strategies and also in implementing any chosen plan. The process involved in selecting the most suitable management strategy is illustrated using data from several hog units. The incorporation of the model into an information system ensures that the model is accessible to farm managers and their advisers.

Key Words: hog production, information systems, simulation model.

Simulation as an investigative tool in farm management has, as yet, failed to fulfill many early expectations (Anderson). This result is attributable largely to researchers' enthusiasm for the model-building aspect of simulation research which has not been matched by corresponding effectiveness in using the models for guidance of real world decision making (Dobson). For a model to be used effectively by farm managers, it needs not only to mimic accurately the real system but also to be accessible to managers. Effective communication between the model and its intended users is most readily obtained by incorporating the model into an information system which includes a comprehensive data collection and transmission service (Blackie). The data required must be readily obtainable by the manager and the information returned from the information system must be in a form that is easily understood by the farm manager.

The purpose of this paper is to discuss the application of a simulation model which may be used by hog farm managers to assess possible outcomes from alternative management policies (Blackie and Dent). This paper reports the results from using the model to evaluate three specific management strategies. The first strategy deals with bred-gilt production, and the second and third involve low and ultrahigh density feeding policies, respectively. Each strategy reflects current farmer interest in reducing feed costs.

The Hog Simulation Model

Efforts in computer simulation have been the subject of a number of recent reviews, a phenomenon which reflects the growth of interest in this area of farm management research (Blackie, Eisgruber, Kennedy, Nelson, Rowe). The computer model described in this paper is incorporated into a business information system which is designed to assist hog farm managers in planning their businesses and in controlling and reviewing the plans. A structure diagram of the decision process involved in using this information system is shown in Figure 1.[1] Information on the hog farm is collected by the farm manager with the assistance of an adviser. These data describe the unit in terms of hog numbers, feeding requirements, expectations of future prices and costs, and future management policies.[2] The

Malcolm J. Blackie is a lecturer in farm management and J. Barry Dent is a professor of farm management at Lincoln University College of Agriculture, Canterbury, New Zealand.

The authors would like to acknowledge the financial support of BOCM/Silcock Ltd. for part of the research reported here. Helpful comments from P. D. Chudleigh, editors, and anonymous referees on an earlier draft are gratefully acknowledged; errors remain the responsibility of the authors.

[1] The information system illustrated in this paper was developed by the authors at Nottingham University, England. It is currently being introduced in Britain by one of the major animal feed suppliers and is on trial in New Zealand (Looker).

[2] To illustrate briefly the data requirements of the model, a farm manager involved solely in fattening hogs for slaughter would need to provide the following information: (*a*) hogs on hand (divided roughly into 5 kg weight classes), (*b*) intended hog purchases, (*c*) intended sale weights of hogs, (*d*) expected costs of feed and purchased hogs and expected prices of hogs sold, (*e*) feeding practices, and (*f*) expected feed conversion efficiency.

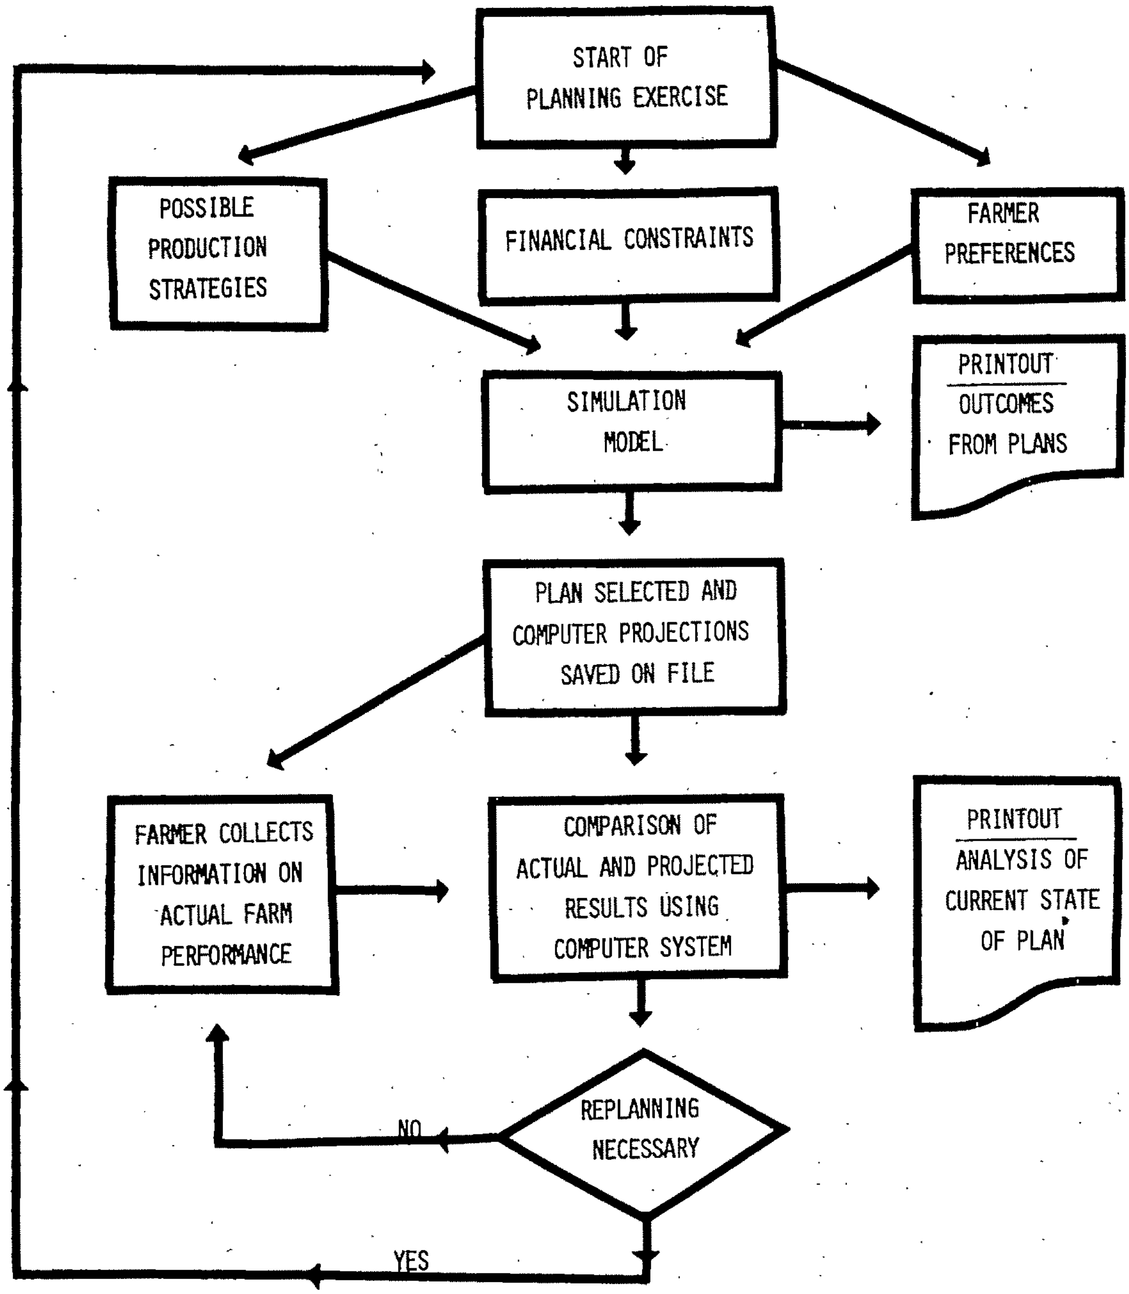

Figure 1. Decision process structure using hog simulation model

data are input to a computer simulation model which produces a detailed forecast of future herd performance. Forecast information includes physical parameters, such as hogs produced, and financial measures such as feed costs, income from hogs sold, and cash flows. The forecast is generally for one year ahead and is divided into thirteen time periods, each four weeks in length. Table 1 includes some of the information contained in the forecast output. Several runs of the model may be made—each run incorporating different assumptions on such factors as feed conversion, capital input requirements, prices and costs, and taxation allowances.

Once a satisfactory forecast has been produced or a strategy selected, the initial input data, termed "setup" data, are stored on a computer file. Every four weeks, the farm manager provides additional data, termed

Table 1. Forecast Output from the Hog Simulation Model

[a] Hogs may be sold at three different weights. For simplicity, the example here shows all sales at one weight.

"period input," on the actual performance of his herd. These data are input to a computer program which produces a period performance analysis, including key efficiency factors such as number of births, average litter size, feed conversion, hog sales, or mortality at various stages. A comparison of these factors with the appropriate model projections (targets) generated by the earlier forecast assists the manager in assessing how closely he is following his intended plan. This process provides the manager with a rapid flow of relevant information on the current state of his business.

Validation tests on the model have shown that model target predictions up to six months ahead are sufficiently accurate for business control (Blackie and Dent). Consequently, targets are automatically revised every six months, but the manager may revise his targets whenever he considers it necessary. For example, a change in hog prices could lead to a different marketing strategy or the performance analysis report might indicate that the planned performance was not being achieved.

The data requirements and the operation of the system have been specifically designed so as to be easily understood by managers and advisers whose knowledge of, and trust in, computer technology may be limited. For instance, experience has shown that managers have more confidence in their own expectations of future prices and costs than in those based on a price-forecasting mechanism. Risk and uncertainty are incorporated into model predictions only to the extent that individual managers define their price and cost expectations. Some managers prefer to include costs such as taxation or mortgage payments in their plans; others choose to ignore these costs. The choice of which costs are to be included in any computer forecast is also a matter of individual choice. This pragmatic approach appears to have been satisfactory to the British and New Zealand farmers who have used the system. However, the authors acknowledge that in situations where price and cost uncertainty are a major part of the market environment, it may be helpful to include an option to predict future prices and costs. A price-forecasting scheme for hog producers has recently been launched in Britain and the authors are watching its progress with interest (Looker).

Investigation of Management Policies

A simulation model incorporated into an information system as described above allows each user of the system to specify his enterprise in detail and to obtain a correspondingly detailed prediction of the outcomes likely to result from any given policy. Of particular interest to practising managers are the target-actual comparisons produced by the information system at regular intervals of time which

assist in overseeing the progress of their chosen plan. The need for information for adaptive management and the use of the model in budgetary control have been discussed by the authors elsewhere (Blackie and Dent). The following section illustrates the use of the model in investigating alternative management policies on hog units in Britain. Financial results from the investigations are expressed as the gross balance between income and expenditure. There has been no explicit consideration of such items as interest charges or taxation effects. Prices and costs used as data in these investigations were deterministic in accordance with the pragmatic approach outlined previously. Although it is possible to select prices and costs stochastically from an appropriate distribution and to include taxation charges, the authors believed that the following investigations would be of greater general interest if these effects were not included. The factors associated with prices, costs, and taxation are influenced highly by local conditions which would have to be explained and defined in each case. The investigations below, therefore, illustrate the use of the model as a planning aid rather than as an information system.

Bred-Gilt Production

Bred-gilt production system involves producing heavy hogs (hogs slaughtered at about 120 kg. liveweight) from gilts which have weaned their first litter of pigs. The basis of this system is the greater efficiency with which the pregnant animal converts nutrients as compared with the nonpregnant animal (English). Of crucial importance are the feasibility of conception in the gilts at an early age and at low body weights, feed conversion rates of pregnant and nonpregnant gilts, the acceptability of the bred-gilt carcass, and feed costs. Brooks and Cole and Pay and Davies suggest that the bred-gilt system is feasible. Bred-gilt production results in a 40% feed saving used per weaner produced (Brooks and Cole). Carcass acceptability of bred gilts does not appear to be a major obstacle. The average litter size in a bred-gilt herd is smaller, leading to a lower production of hogs over a given time period than would be expected from a similar sized conventional breeding herd. These data were used to examine the bred-gilt production system under three alternative policies. Policy A refers to heavy hog production from a conventional breeding herd. Policy B refers to the production of heavy hogs and bred gilts with about the same number of breeding animals as in policy A. Policy C refers to the production of heavy hogs and bred gilts from a number of breeding animals that will produce about the same number of slaughter hogs as policy A.[3]

Table 2. Data Used to Compare Bred-Gilt Systems with Conventional Heavy Hog Production

Age pigs weaned	2 weeks
Age pigs transferred to fattening house	10 weeks
Age of hogs at sale (average)	34 weeks
Liveweight of hogs at sale	118 kg
Number of pigs born per litter (bred-gilt system)	9
Number of pigs born per litter (conventional system)	10
Age of gilts at transfer to breeding house	26 weeks
Age at which gilts are bred (bred-gilt system)	29 weeks
Age at which gilts are bred (conventional system)	38 weeks
Farrowing index (litters per sow per year)	2.4
Age gilts sold for slaughter (bred-gilt system)	49 weeks

Each alternative was examined using the hog simulation model. Table 2 outlines the main assumptions. All animals sold for slaughter (heavy hogs, cull sows, and bred gilts) were assumed to be sold at $82.00.[4] This represents a price of $0.88 per kilogram deadweight for heavy hogs and bred gilts and a lower price (around $0.66 per kilogram deadweight depending on sale weight) for cull sows. Rations fed to the different groups of hogs under the bred-gilt systems were the same as those fed to the conventional unit. The bred gilts were fed as heavy hogs until they farrowed in accordance with the practice recommended by Brooks and Cole. Policy A in table 3 is comparable to policy C in terms of average annual fattening house fill.[5] A larger breeding herd, as shown by policy B, resulted

[3] The effort involved in adjusting the data to produce exact comparisons was not justified in view of the wide differences in profitability between the alternatives (see table 3).

[4] Prices expressed in this paper are in New Zealand dollars.

[5] The model can predict the percentage fill (the ratio of numbers of hogs to hog places) in the fattening house and this index may be used as a guide to the effectiveness of utilization of fattening facilities.

in considerable overcrowding in the fattening unit. Total hog sales (table 3) were significantly less in all bred-gilt systems as gilts were not available for slaughter until forty-nine weeks of age as opposed to the thirty-four weeks average slaughter age of heavy hogs. As bred gilts occupied the fattening unit until twenty-six weeks of age, there was little scope for increasing the annual throughput of hogs by increasing the size of the breeding herd. At the prices used in this set of investigations, bred-gilt production using early weaning did not appear financially viable. The saving in feed achieved using bred-gilt production did not compensate for the loss of income resulting from the reduced sales of hogs. This conclusion remained valid for the study farm when the above alternatives were examined with pigs weaned at six weeks as opposed to two weeks.

Use of Dried Poultry Manure in Hog Rations

Dried poultry manure (DPM) is currently being offered commercially as "filler" and a source of minerals in hog rations. Recent studies have indicated that at levels of up to 30% DPM, health and carcass quality were not adversely affected (Perez-Aleman et al.). However, for each 10% increment of DPM, growth rate decreased by 0.02 kilogram per day, feed conversion efficiency fell by 0.25 units and killing out percentage was reduced by 0.96. In order to assess the economic potential of this feeding practice, data were collected from a hog unit considering the use of DPM in fattening hog rations.

The unit used in this investigation comprised a breeding herd of 152 sows which sold hogs for slaughter at 89 kilograms liveweight. Three policies were considered for this unit. The first is based on the current farm feeding practice and the remaining two assume 10% and 20% DPM in the final finishing ration for hogs, respectively. The effect of DPM in the finishing diet was simulated by altering the growth rate, feed conversion, and killing out percentage parameters included in the data input to the last two policies to correspond to the research findings of Perez-Aleman et al.

The killing out percentage of hogs where DPM was not fed was 75% and the average age at slaughter of these hogs was twenty-eight weeks. Under all three policies, pigs were weaned at five weeks weighing 11 kilograms and introduced to a starter diet. Feed conver-

[a] System balance is balance of all costs and receipts for each system including some minor costs not shown in this table.

sion on this diet was 2.0 and hogs reached 34 kilograms five weeks after weaning and had a maximum feed intake of 1.3 kilograms of feed per day. The starter diet did not include DPM in any of the three policies. From 34 kilograms to slaughter, hogs were fed a finishing diet which contained either 0, 10%, or 20% DPM. The maximum rate of feeding for the finishing diet was 2.1 kilograms per day. Feed conversion where DPM was not included in the diet was 2.8 during this stage. Hogs under all three policies were sold at $0.32 per kilogram deadweight. At each level of DPM, i.e., 10% and 20%, three model runs were made, each with a different breeding herd size. The policy assuming no DPM was used as the basis for comparison and the model runs were grouped into three series. In series 1, each run assumed an identical breeding herd. This assumption resulted in increased pressure on fattening facilities for the two policies which included DPM in the feed since a slower throughput of hogs was involved. In series 2, the breeding herd was increased in size (for the two policies using DPM-based feed) to give a similar annual throughput of hogs as the policy which included no DPM in the feed. This resulted in even greater overcrowding in the fattening unit. In series 3, the breeding herd was decreased (for those policies where DPM was included in the feed) to keep the average annual fill of the fattening house similar to the policy which used no DPM.

Table 4 details the major physical and financial results from this investigation. In all cases, no charge was made for DPM. At zero cost, DPM could be included in the diet at the 10% level with little effect on the system balance. Most effect at this level of inclusion is evident in series 1 where the breeding herd size was identical for all policies. Twenty percent inclusion resulted in a major drop in the system balance in all cases where DPM was included in the diet. The increased feed requirement where DPM was fed (caused by the slower growth rate) more than compensated for the savings in feed costs. DPM, therefore, is unlikely to prove an economic proposition when fed under the conditions of this investigation.

Nutrient Density Investigation

A third feeding practice currently attracting research and commercial attention is the use of high-density feed. Such feed contains the same nutrients as conventional feed, but in a more concentrated form. Provided that the absolute nutrient intake per time period is not altered, hogs should exhibit similar growth patterns when fed diets of different concentrations (Filmer). Since efforts are currently being made to promote the use of high density feed, an investigation was set up to determine the break-even costs of certain high-density feeds which are offered commercially.[6] This investigation was based on a farm situation where hogs were sold at 82 kilograms liveweight with a killing out percentage of 71. Two basic policies were considered. First, the use of conventional feed for all animals in the unit was assumed. Second, the use of high-density feed for all fattening hogs was assumed, with breeding hogs and young pigs still being fed conventionally. Different growth rates of fattening hogs were also examined under the second policy to test the sensitivity of this policy to assumptions on growth rate (breeding herd size was adjusted to maintain a similar average fattening house fill at each rate

[6] Using high-density feed, Filmer and Cooke suggest the possibility of a higher rate of gain and improving killing out percentage (thus reducing feeding time to achieve the same carcass weight) at the same level of nutrient intake. This last effect is due to the reduced gut size and fill on such a diet (Filmer).

Table 4. Physical and Financial Parameters for Herds Using DPM in Fattening Hog Rations

Herd Size (sows)	Series	Dietary Inclusion Rate of DPM (%)	Total Hogs Sold	Total Fattening Feed use (tons)	Average Fill of Fattening House (%)	Income from Hogs ($)	Fattening Feed Cost[a] ($)	System Balance ($)
152	1	0	2,523	595	100	105,392	68,164	17,436
152	1	10	2,454	619	104	102,508	66,360	16,492
152	1	20	2,379	645	109	99,384	69,240	10,352
154	2	10	2,521	635	106	105,442	68,020	17,228

	Finishing	2.7	4.5
High-density	Starter	1.4	2.1
	Finishing	1.4	2.3

of growth). Under both policies, pigs were transferred to the fattening house at ten weeks at a weight of 27 kilograms and introduced to a grower diet which was either conventional or high-density. These were fed for five weeks and then a conventional or high-density finishing diet substituted. The basic feeding regime for both policies appears in table 5. Diet cost was assumed the same ($102 per ton) for both feeding methods but the rate of feeding for the high-density feed policy was restricted so as to achieve grading results comparable to conventionally fed hogs (Filmer; Filmer and Cooke). Model predictions for the various alternatives are summarized in table 6. Alternative 1 represents the results from the herd when fed a conventional diet and with most hogs achieving sale weight at twenty-six weeks of age. Alternatives 2–5 represent the same herd but with a high-density feeding regime for all fattening hogs—each alternative assuming a different growth rate in the fattening unit. The enterprise balance in this set of runs was clearly in favor of the high-density feed (table 6). As the price of high-density and conventional feed was assumed the same, it can be seen from table 6 that the difference in system balance between the two feeding practices is attributable to the savings in feed use under high-density feed regimes.

Under the conditions of this investigation, it proved economical to feed high-density feed at a cost of up to 110% above conventional feed if two weeks saving in time of slaughter was possible. This may well prove feasible if the improvements in growth rate and killing out percentage mentioned previously can be achieved in commercial practice. Where hogs fed high-density feed reached slaughter at the same age as conventionally fed hogs, a 62% premium was the maximum justified for high-density feed and this fell to 38% if high-density feeding resulted in an average age at slaughter of twenty-eight weeks. These results suggest that high-density feed could prove of economic benefit to the individual farm manager.

Conclusions

Simulation models have a considerable potential for use in assisting managers in investigating alternative management policies. However, as yet this potential has not been fully realized largely due to the nature of the models built. This paper has discussed the use of a hog simulation model in an investigationary mode and has illustrated this use in relation to possible management strategies for individual herds. The alternatives discussed in this paper show clearly the wide gap between promising research and its application at the farm level. Both the bred-gilt system and the use of DPM in hog feed offer significant potential savings in feed cost. However, the nature of the herds on which these methods of production were tested were such that feed cost savings were more than offset by a slower throughput of hogs. The ultrahigh-density feed investigation showed the sensitivity of this production method to changes in growth rate. A model of the sort described here may ease the communication problem between researchers and practitioners by providing a common medium on which research results may be evaluated for individual circumstances.

The hog simulation model and the accompanying information system are attempts to allow farmers access to the power of a compu-

ter in a way which is easy to use and which produces meaningful results. It is intended, in the near future, to incorporate a feed formulation service into the information system. This facility will be of major benefit in the New Zealand situation where most hog producers mill and mix their own feed. Other additions, such as price forecasting mechanism, could be appended to the model with little difficulty in order to make the model more useful in particular local circumstances. The main direction of ongoing work on the hog information system is in developing the system from a pilot scheme into a fully operational management service in cooperation with the New Zealand Pork Industry Council. (Readers interested in using the system should write to Malcolm Blackie.) The methodology developed for the hog simulation model is also being used to develop similar models for other farm enterprises.

Economic Impact of Restricting Feed Additives in Livestock and Poultry Production

Thomas Mann and Arnold Paulsen

Effects of feed additive restrictions on meat production have been measured in previous studies. An econometric simulation model is used in this study to evaluate the impact of policy alternatives on costs, prices, and net profits in beef, pork, broiler, and turkey production over a ten-year period. Under the model, all the restrictive policy alternatives produced wholesale price increases. Simulation estimates of price and production cost increases, however, were lower than previous findings. Health risk reductions may be obtainable at a smaller loss in economic efficiency than previously suggested.

Key words: economic efficiency, feed additives, health risk, simulation.

The restriction or elimination of feed additives in livestock and poultry production has become a significant public policy question as a result of concerns voiced about potential public health hazards associated with such additives. Federal regulations have been established primarily to guard consumers from allergic or toxic reactions to meat products containing additive residues. A second potential hazard, which has been identified more recently, is that continued subtherapeutic applications of antibiotic additives may produce bacteria immune to classes of antibiotics. Any development that would make humans more susceptible to disease necessitates a reevaluation of a technology, despite its proven profitability.

Policymakers are attempting to meaningfully relate health risk reductions to changes in economic efficiency to accurately predict the impact of regulatory restrictions on production. Restricted use of feed additives could reduce productivity of animal feed and might cause significant changes in swine and poultry housing methods. In addition, the quantity of meat marketed would probably decline and retail prices rise. To make accurate predictions, it is necessary to establish valid measures of health risks and their effects on economic efficiency.

This paper uses one technique to estimate the costs of a restrictive policy in terms of expenditures and consumption for meat. Quantitative estimates of returns to producers and costs to consumers over time are provided, and the distribution of these impacts among producing and consuming groups is described. We have used an econometric model to simulate the livestock and poultry industries. The recursive model consists of forty-two sequential linear equations to approximate production and marketing relationships of live animals and meat in the United States and is fitted by least squares with quarterly data from the period from 1962 through 1972.

Feed activities analyzed include subtherapeutic chemical and biological additives to livestock and poultry feed which stimulate growth, increase feed efficiency, and reduce mortality. These include growth hormones such as Diethylstilbestrol (DES) and Melengesterol Acetate (MGA), as well as antibiotics. Antibiotics include the true antibiotics (tetracyclines and penicillin) and the synthetic antibiotics (sulphonamides, nitrofurans, and arsenicals), all of which inhibit subclinical infection and microbial growth in the digestive tract and circulatory system.

Thomas Mann is a research economist at Quaker Oats, Co., Chicago, and Arnold Paulsen is a professor of economics at Iowa State University.

Journal Paper No. J-8322 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa; project 1981.

Previous Research

Previous studies analyzed the economic impact of eliminating the use of DES and antibiotics. All previous studies, however, used a comparative statics analysis: comparing the equilibrium of a preban period with the equilibrium of a postban period. Such studies determined the impact of the ban on equilibrium farm prices, retail prices, and per capita consumption. Studies by Paulsen and Butz analyzed the impact of restricted use of antibiotics in swine production. A U.S. Department of Agriculture study (1971) analyzed the impact of eliminating DES. This research also analyzed the welfare impacts of higher feed grain usage. Another USDA study (1972b) also published in Gilliam et al. considered the economic impact of banning subtherapeutic use of antibiotics in broiler and turkey production.

The comparative statics studies did not trace out the time path of adjustment. For example, the USDA study (1971) postulated two possible producer responses to a ban on DES. In the first case, the same number of animals would be fed for a longer period of time and marketed at the same weights as in the preban period. Producers would simply use more feed over a longer time period for the same number of animals to achieve the same total output, which would sell at the same price as before. In the second case, cattle numbers were held constant, but the animals were marketed at lower weights. A comparative statics framework permits the analysis of both types of situations since two equilibriums of the same time length can be compared.

If cattle on feed at the time of the DES ban actually experience a lower than normal rate of daily gain, the market will certainly be presented with a smaller total tonnage of beef in every time period. It is possible that the number of steers on feed will increase in response to higher prices, but a smaller tonnage of beef must be accepted per month in the transitional period. Slowing the rate of gain would cause a onetime reduction in beef production and raise prices just as speeding up the rate of gain by the adoption of DES caused a onetime increase in production and reduced prices. DES adoption, however, occurred over several years, and the effect was less discernible. The complete elimination of both DES and antibiotics at the same time (during the transition period) would reduce output each quarter below the level existing before the ban and below the eventual equilibrium level.

Method

The simulation model improves upon the comparative statics approach by accounting for, and estimating the impact of, withdrawal of feed additives on feed productivity or feed efficiency. Reduced feed efficiency will raise producer costs and reduce feed-to-meat conversion ratios. Reduced feed efficiency can be expected to reduce feeding rates per head per day and cause a search for other factors to substitute for feed at the margins if possible. Reduced feed efficiency results from reduced daily rate of gain. This raises the proportion of feed used for basic metabolism or maintenance and thus raises feed costs per unit of gain and lowers supply of grain-derived meat at any given price relationship between meat and grain.

The USDA (1972a) report on DES and antibiotics used expert judgment and pharmaceutical industry estimates of rate of adoption of feed additives. This study in contrast uses the results of two sample surveys of adoption rates done in Iowa. The USDA assumed antibiotic usage was 80% of all steer and heifer cattle marketed in 1970 and 90% of all growing pigs. Hutton in 1971 estimated that 34% of cattle on feed and about 85% of hogs on feed were being fed antibiotics. In a 1972 survey of Iowa swine producers, James and Beneke reported that 84% of growing pigs were fed rations including an antibiotic. For the purposes of this study, the authors relied upon the Hutton study and assumed that 31% of steers and heifers marketed and 75% of all barrows and gilts marketed were fed antibiotics.[1]

The simulation model used covers the United States and includes beef, hogs, lamb, broilers, and turkeys. It was constructed by Rahn and modified by Mann et al. It can estimate the impact of feed additive prohibitions by simulating the meat animal markets with and without feed additives. Prices, per capita consumption, resource returns in livestock

[1] It cannot be proven at this time that projections based on Iowa samples are more accurate than the USDA assumptions. However, we view the surveys as the best available evidence. The use of lower adoption rates does reduce the consequences of removing feed additives. Estimates on rate of adoption from the Iowa surveys are presented in Mann as well as estimates on average rate of gain, feed efficiency, and mortality.

production, and total costs to the consumer can be compared between the simulations with and without feed additives. The simulation presents estimates for each quarter during the transition period.

To simulate the ban of feed additives, the biological or physical relationships in the model were adjusted, but the market relationships were held constant. The biological impact of banning feed additives was simulated through appropriate adjustment of selected physical coefficients. Three biological responses were explicitly acknowledged for each livestock and poultry class: first, lower daily rate of gain; second, increased feed and other input requirements per unit of meat; third, higher mortality and lower reproduction rates. Stock-to-slaughter coefficients and reproduction variables like pigs saved per litter were reduced to reflect increased livestock and poultry mortality.

For antibiotics, three series of adjustments were entered in the model for each animal class. First, the immediate impact of the change in rate of gain on livestock numbers coming to market was indicated by shifting a percentage of animals for slaughter from one quarter to the succeeding quarter. The percentage was calculated as the estimated rate of adoption multiplied by the estimated improvement in rate of gain due to antibiotics.

We believe that the absolute values of most variables in our quarterly simulation model are relatively credible within six to eight quarters, but beyond that range particular values quickly acquire a wide confidence interval. Short-term estimates are based on more accurate forecasts of exogenous variables. Nevertheless, the model's alternative long-run simulations still serve long-term analysis by estimating deviations from the benchmark, that is, they indicate change in trends in livestock associated with banning feed additives.

To illustrate, a detailed examination of the adjustment for hogs is presented. In the Mann et al. simulation, the barrow and gilt slaughter equation is

$$(1)\quad HBGQ\,(I) = -5910.8 + 338.8D4 + 2886.1D3 + 4031.1D2 + 39.67\$HP(I\text{-}1) + 5.246\ HPI(I\text{-}2) + 0.6243\ HSFQ(I\text{-}2)\cdot HPSL(I\text{-}2) + 0.3984\ HSFQ(I\text{-}3)HPSL(I\text{-}3).$$

(For definition of variable refer to table 1.) The hog profitability index is

$$(2)\quad HPI(I) = HP(I) - HTC(I).$$

Equation (1) estimated that in the preban period approximately 62% of the barrow and gilt slaughter in current quarter I comes from the pig crop ($HSFQ \cdot HPSL$) in quarter I-2, and 39% from the pig crop in quarter I-3. This is an average biological rate of maturation which was adjusted downward as a result of banning feed additives.

To reflect the effect of the antibiotics ban in reducing rate of gain, numbers of hogs marketed for slaughter were reduced and delayed. The coefficients relating the pig crop ($HSFQ \cdot HPSL$) to hogs sold ($HBGQ$) were adjusted. Because aggregate rate of gain was reduced by 9.025% (75% rate of adoption times 10.7% decrease in rate of gain), this implied that 8.025% fewer butcher hogs would be coming from the I-2 pig crop and 8.025% more barrows and gilts would be coming from the I-3 pig crop. Hence, the new equation for barrow and gilt slaughter is

$$(3)\quad HBGQ(I) = K + 0.5742\ HSFQ(I\text{-}2)\cdot HPSL(I\text{-}2) + 0.4304\ HSFQ(I\text{-}3)\cdot HPSL(I\text{-}3),$$

Table 1. Variables in the Equations

Variable Notations	Variable Identification
HBGQ	Barrow and gilt slaughter (1,000 head)
HSFQ	Sow farrowings (1,000 head)
HPSL	Pigs saved per litter
HP	Hog price ($/cwt.)
$HP	Change in hog price ($)
HPI	Hog profitability index ($/cwt.)
I, I-1, I-2, etc.	Quarter: I = current, I-1 = last quarter, etc.
D2, *D3*, *D4*	Seasonal variables to adjust the intercept constant for second, third, and fourth quarters
SBMP	Soybean meal price, 44%, Decatur ($/ton)
FLW	Farm laborer's wage (excludes room and board)
HTC	Hog total cost ($/cwt.)
CP	Corn price, #3 yellow, Chicago ($/bu.)

where K equals all the other variables in the original equation.

The second adjustment indicated the impact of changes in feed efficiency and rate of gain on production costs. Because rate of gain was reduced by 8.025%, feed efficiency is reduced by 3.825%, according to Mann. Reduced feed efficiency raised producer costs through the hog total cost variable in the hog profitability index. The feed requirement of hog total cost was increased by 3.825% to reflect the aggregate impact of decreased feed efficiency. Labor requirements were increased by 8.025% on a per hundredweight basis because more labor is needed when it takes longer to produce 100 pounds of pork. Fixed capital or overhead requirements per hundredweight were increased by 8.025% because less pork would be forthcoming from the same physical facilities per year but with the same operating costs. The old and new hog total cost functions, which are on a per hundredweight basis, are

(4) $HTC(\text{I}) = (1.559\ CP(\text{I}) + 0.0075\ SBMP(\text{I}))\ 6.05 + 1.27\ FLW(\text{I}) + 3.0,$

and

(5) $HTC(\text{I}) = (1.559\ CP(L) + 0.0075\ SBMP(\text{I}))\ 6.28 + 1.37\ FLW(\text{I}) + 3.25.$

Thus, the adjustment of the biological variables of the model affected not only immediate barrow and gilt slaughter, but also the hog profitability index, which in turn affected sow farrowings, sow slaughter, and average slaughter weight in future periods.

The removal of antibiotics would probably increase mortality of pigs and thus reduce pork marketings in the third and fourth quarters after the ban and permanently reduce sow herd efficiency. More pigs, especially baby pigs, would die without the prophylactic protection of antibiotic feed additives. This increase in mortality was estimated to be similar to the decrease in mortality associated with the adoption of antibiotic feed additives in the early 1950s. Paulsen and Mann report the results of a regression analysis of national and Illinois pigs saved per litter since 1930. The best fit was obtained by a linear regression shifted upward about one-third pig per litter in 1953. Thus, the exogenous variable pigs saved per litter (*HPSL*) in the barrow and gilt slaughter (*HBGQ*) equation of the simulation was adjusted downward by one-third pig per litter for sows farrowing after the ban of antibiotics.

The combined result of all the adjustments made in the simulation was a reduction in number of hogs marketed and a reduction of resource efficiency in pork production. Similar procedures were used in the beef, broiler, and turkey sectors to adjust historical, biological, and cost coefficients for the removal of feed additives. (Adjustments are presented in Mann, tables 5-4 through 5-8.)

The model generated quarterly values of the endogenous variables for each of four simulations. For the purposes of this presentation, the following variables are discussed: (*a*) beef, pork, broiler, and turkey wholesale prices (quarterly), (*b*) cattle feeder and hog producer net profits (quarterly), and (*c*) total consumer expenditures at wholesale level (yearly).

Results

Simulation One: Benchmark

The endogenous variables in live animal and meat markets are simulated from the first quarter of 1973 through the fourth quarter of 1979 assuming continued use of feed additives. The demand and supply equations reflect average relationships of 1962–72. The level of income and population for the future reflect continued growth. Feed prices were returned by 1977 to $1.75 per bushel of corn, just above 1972 levels.

Simulation Two: Banning Antibiotics

Only antibiotics would be restricted as animal feed additives in poultry feeds and in hog and cattle feeds as of July 1, 1973. The possibility of a residual effect after the effective dates exists. Therefore, reduction in feed efficiency, rate of gain, and increased mortality on poultry were assumed to begin the second quarter of 1973 and to begin affecting hogs and cattle in the fourth quarter of 1973. The pattern of production tended immediately downward. Upward change in wholesale prices from the first quarter of 1973 through the fourth quarter of 1977 are given in table 2.

The major effect of the antibiotics restriction was felt in the pork production sector. Wholesale pork prices began to rise three months after the ban in late 1973, peaking at a price increase of $3.91 per hundredweight in the first quarter of 1975. This increase was 4.5% greater than the simulated wholesale price with antibiotics for the same quarter.

Table 2. Difference in Wholesale Prices from Benchmark Simulation

Farm level hog prices rose more than $2.00 per hundredweight in the same period, and net profits to pork producers rose $4.42 per head, or 4.5%, over the benchmark.

Although many pork producers have resisted the feed additives ban, simulation analysis indicates that the simultaneous withdrawal of feed additive technology from all pork producers would not lead to financial disaster for the average hog producer. Individual and total production would decline, but prices would increase more than proportionately, at least temporarily, pushing average profit of hog production up after the ban.

The estimated price of broilers and beef would also rise as a result of an antibiotics ban and could peak in the first quarter of 1975. At this point, the wholesale beef price was $0.66 per hundredweight (or 1.1%) above the benchmark; the wholesale broiler price was $0.77 per hundredweight (or 2.2%) above the benchmark. The turkey sector peaked in the third quarter of 1975 when the wholesale turkey price was $1.25 per hundredweight (or 3.4%) above the benchmark.

At the wholesale level in the postban simulation, total consumer expenditures for meat are estimated to increase $500 million over the simulation with antibiotics for the same seven-year period.

After three years of the antibiotics ban, higher farm and wholesale prices for livestock and poultry stimulated increased supplies, which, in turn, narrowed price differentials and reduced returns per head to about normal preban levels. The long-run effect of the antibiotics ban for hogs is higher consumer cost but little change in pork producer profitability.

Simulation Three: Banning DES

Because DES is used only with steers to simulate the market effect of its ban, adjustment of model coefficients was required only in the beef sector. The resulting wholesale meat price differentials are presented in table 2. The impact on the beef sector was significant and continuous. Price increases for wholesale beef peaked in 1975 at $4.86 per hundredweight (or 7.4%) over the benchmark. The impact of banning DES also spread to pork, broiler, and turkey wholesale prices. The peak effect on these related meats occurred a year later in 1976. Another major impact of the DES ban is first to increase and then to reduce the average cattle feeder's net profit. Estimates of net profit per head were increased up to $3 per head in the first year, then permanently reduced by the DES ban throughout the rest of the simulation by $3 to $10 per head.

Because beef supplies decline and wholesale and retail prices increase while producer net returns fall after the first year, it seems that reductions in the rate of gain and feed efficiency resulting from the DES ban would adversely affect most everyone. Net profits to cattle feeders would be reduced because the simulation estimates that cattle feeders would be unable to pass increased costs on to consumers as they did in the case of the antibiotics ban. Consumer expenditures for beef would rise $2,356 million over the five-year, postban, simulation period.

Simulation Four: Banning Antibiotics and DES with Replacement Technology

This simulation acknowledged the possibilities of replacement technology. Antibiotic replacement technology exists or is within a year or so of perfection. It consists of adopting compounds of tylosin and bacitracin in place of compounds containing tetracyclines, penicillin, and sulfonamides. Technological replacements for DES currently consist of the implants Synovex and Ralgro for steers, and Synovex and MGA for heifers. Even if Synovex is eventually found to contain a carcinogenic estrogen and banned, two other alternatives now exist and others may be developed.

Replacement technology simulation forces the analyst to address several questions. How quickly will this technology be available and adopted? Will the technological alternative be equally effective? Will enough replacement compounds be available at prices equivalent to those of original compounds to insure rapid adoption of the substitute? Will successful adoption of new compounds involve any changes in facilities or management that would keep adoption levels of the replacements below those of the previously banned compounds? A perfect substitute will probably not be found. Replacement technology, however, was assumed to be equivalent to original technology in all the areas mentioned. Replacement technology was assumed available one year after the ban of the unacceptable compound and gradually adopted over the second year to the effective level of the original technology.

Wholesale prices greater than their benchmark levels are simulated during the ban. A

year after the replacement technology has been completely adopted, however, wholesale prices of both the beef and pork have dropped below the benchmark projections. The stimulation to supply, provided by increased prices during the ban, produced lower prices later when combined with replacement technology. Total consumer expenditures during the simulation would be expected to increase over the benchmark.

Conclusions

Simulation seems to be a valuable tool for environmental impact analysis. The accuracy of this particular simulation cannot be conclusively established here. It does seem to depict the theoretically expected pattern of impact and adjustment over time.

The major impact of banning antibiotics in 1973 would have been a permanent increase in prices and a temporary increase in producer net return simulated to take effect in five to seven quarters. The same pattern would be expected in removal of any technology, but exact degree and time lag would be unique to each technology and economic sector.

The contribution of technology is determined by both biological and behavioral response patterns. The presence of cross-price elasticities of demand between pork and other meats allowed the effect of reduced production in pork to be spread over the larger meat sector. The output reduction in the pork sector was only slowly and partly offset by expansion in poultry production.

In the Gilliam et al. study of antibiotics restrictions, total annual consumer expenditures for beef, veal, and pork would increase more than $1.6 billion. This simulation estimates about $500 million over five years. In the USDA study (1971) of DES restrictions on beef, per capita consumption declined 3.7% (carcass weight) and retail beef prices increased about 3.6%, for a total annual expenditure increase of $458 million. In this simulation, consumption decreased by 2% to 3.25%, wholesale prices rose 4% to 6%, and consumer expenditures rose $2.3 billion in five years.

The trade-off between public health and food production costs remains to be evaluated for public policymakers. This study attempts to structure the policy trade-off. Quantified estimates of the improvement in health from banning antibiotics and DES are urgently needed. The banning of antibiotics and DES is certainly not final nor is it the last of this type of policy decision to be made. Society faces a continual challenge to accurately weigh environmental risks and economic efficiency. Analytical tools will have to be appropriate and accurate if intelligent, collective decisions are to be made. Well-formulated simulation is one tool that can improve the decision-making process.

The Value of Information and the Value of Theoretical Models in Crop Response Research

Richard K. Perrin

The concepts of the value of information and the value of alternative models are developed and applied to corn response research in Brazil. Soil test information was worth as much as $30 per hectare and the response model employed was worth up to $23 per hectare, but two soil classification models had negative values.

Key words: fertilizer response, soil testing, value information.

When production functions first began to be applied to the economic analysis of crop response to fertilizer, the primary methodological problem seemed to be the choice of the algebraic form of the function. But soon, other troublesome questions appeared. How should the profit-maximizing principle be altered in recognition of farmers' risk aversion? Data from different experiments, or even from the same experiment in two different years, often gave rise to quite different optima. How are these results to be reconciled? Should the data from different sites and different years be combined? And since each additional experiment gives yet another optimum, how long should one keep on experimenting? Furthermore, most farmer recommendations are based on the soil's classification and on soil test results—how can these factors be systematically incorporated into the response-analysis approach?

These and other questions related to the economics of crop response research and fertilizer recommendation procedures are quite important in view of the considerable sums of money expended around the world in conducting response experiments, in testing soils, and in making recommendations to farmers. The thesis of his paper is that these questions can be best understood within the context of the economics of information. Two concepts, the value of information and the value of alternative models, are described. The concepts are then used to examine the value of two alternative production function models and three soil classification schemes and the value of soil test information in the analysis of corn response data from Brazil.

The Economics of Information Applied to Response Research

The type of research at issue here is applied response research, the results of which are intended to be of direct use to persons who must make production decisions.[1] In order to establish a framework for evaluating such research, we must begin with the decision maker and the decision which is at issue. The decision variable of interest here is the level of fertilizer to be applied to a crop, designated as the vector F. The outcome, or payoff, from the decision is the net return to fertilizer use, defined as the value of the crop obtained minus the cost of the fertilizer.

The payoff is related to the decision through some imperfectly understood and imperfectly controlled production process. The arguments of the production process include not only F but a host of other variables, only some of

Richard K. Perrin is an associate economist with the International Corn and Wheat Improvement Center and an associate professor of economics at North Carolina State University.

The author wishes to thank Bruce Bullock, E. C. Pasour, Jock Anderson, Robert Cate, the Brazilian Ministry of Agriculture, the editor, and an anonymous reviewer for helpful comments on earlier drafts of this paper. Of course they bear no responsibility for remaining errors. This study was supported in part by the Agency for International Development, contract AID/csd-2806.

[1] Much agronomic research is also, or perhaps exclusively, more basic in nature, designed to reveal a greater understanding of the production mechanism, with little or no direct relevance to the farm decision-making process. Such research must be evaluated on some basis other than that developed here.

which can be controlled or even identified. This imperfectly understood production process can be approximated by some theoretical model, or production function, such as

(1) $$Y = g(F, C, T, W, e),$$

where Y is crop yield, C represents site characteristics as embodied in a classification of the soil by some taxonomic system, T represents site characteristics as measured by soil tests, W represents weather or any other factors of production which can be measured but not controlled or predicted, and e is a residual term representing the effects of other unidentified factors in the production process.[2]

Each of the arguments of equation (1) can be interpreted either as vectors or as scalars. The payoff is related (approximately) to the decision variable as

(2) $$\Pi = p\, g(F, C, T, W, e) - PF,$$

where p is the value of additional units of yield and P is the price of fertilizer. Since the random variables W and e cannot be observed prior to the decision, the payoff itself is a random variable for any given level of fertilizer, F.

This representation of the decision problem is not particularly novel, but it emphasizes an aspect of the problem that is too often ignored in fertilizer response research. This is the fact that the production process is contingent upon the characteristics of the individual site, as well as upon weather and fertilizer application. Since the soil classification and soil test variables vary from site to site, the optimum F also varies from site to site.[3] The decision maker must make fertilizer decisions for a whole population of sites, and this is true whether the decision maker is an individual farmer or a remote decision maker making recommendations to farmers.

Consider now the implications of the above conceptualization for a decision maker who begins with very little information about the optimum fertilizer levels, F, for his population of soils. The decision maker can search for information about the relationship between his decision variable, F, and his payoff. He can search for a number of kinds of information in various amounts, presumably guided by the principle that information should be acquired as long as its value exceeds the cost of obtaining it. The decision theory advanced by Schlaifer and used by a number of agricultural economists provides a framework for estimating the economic value of any particular piece of information. To paraphrase Schlaifer, the value of a bit of information is the difference between the decision maker's current expectations of (a) the payoff value that will result if he chooses his act as well as he can without obtaining the information, and (b) the payoff value that will result if he were to obtain the information and then choose his act as well as he can. In other words, the value of the information is the increment in expected payoff that can be realized by utilizing the information in making the decision.

In choosing a fertilizer level, accepted theory implies that expected utility, rather than expected dollar payoff, provides the criterion for choosing among alternative fertilizer levels. As a first approximation, however, the value of information can be described as the increment in expected dollar payoff which can be realized by utilizing the information. If the expected dollar value of the information is small relative to the decision maker's total wealth or if the decision maker is risk-indifferent, the criterion of maximum expected dollar payoff is equivalent to the criterion of maximum expected utility. Furthermore, the money equivalent of the increment in expected utility must be smaller than the increment in expected payoff, at least for risk averters. Expected payoff thus provides an upper bound estimate of the value of information.

The first step in searching for information is to draw a sample of production sites and obtain from them some observations on the production process represented by equation (1). With respect to this stage of research, two important questions have been explored in the literature. First is the question of the optimum sample size, i.e., the number of experiments to conduct either in a given year or through time. This question has been explored by Anderson and Dillon, and while it is a significant question, it will not be addressed in this paper.

[2] Statistically, this specification of the production process is not and cannot be a very happy one. We do not know and can never know the "true" specification of the process. If such a thing exists at all, we will misspecify it by omitting variables, choosing the wrong algebraic form, and measuring the variables inaccurately. We should therefore be more concerned with testing the hypothesis that this theory predicts better than the next best alternative, rather than the hypotheses that the coefficients of some particular algebraic specification equal zero.

[3] This is true for either an *ex post* optimum (after weather and other time-dependent variables can be observed) or an *ex ante* optimum (before these variables can be observed). But we will be concerned here with the *ex ante* optimum, since it is the only one relevant to this particular decision process.

The Value of Alternative Response Models

A second question which has received a great deal of attention is the appropriate choice of a model (variables and algebraic form) to specify the response function (1) for estimation. Most of the literature dealing with this choice has dealt with statistical criteria for making the choice among response models, but two studies (Havlicek and Seagraves, Anderson) have raised the question of the economic value of alternative models. Extending Schlaifer's logic, the economic value of a production model can be defined as the difference between the decision maker's current expectations of the payoff value that will result if he chooses his act using the production model in question and if he chooses his act using the next best production model available. In other words, the value of a response model is the increment in expected payoff that can be realized by using that model rather than the best alternative model in making a decision.

Both of the studies just cited calculated the economic value of a production model under the very restrictive assumption that the response model in question, as estimated, is the underlying production model. Since it is impossible for us to ever know the true model, a more realistic (though more expensive) method of determining the value of a model is to draw new samples (experiments) from the production population to obtain an estimate of the difference in expected payoff between the decisions based on the model in question and those based on the alternative model.

The Value of Soil Test and Soil Classification Information

Once the decision maker has collected data and estimated the production function (1), he must decide how much information to obtain about each site prior to making the fertilizer decision for that site. One aspect of this problem is the simple question whether he should determine the soil class, C, and/or obtain a soil test, T, for each site for which he must make a decision, that is, should a uniform amount be applied to all sites, or should the amount be tailored to each site? Furthermore, additional information may be obtained about probable values of the weather variables, W, for the current season. In each of these instances, there will be a cost to obtaining the information, which must be weighed against the value of the information. The value of any one bit of information can be defined as before, i.e., the increment in expected payoff which can be realized by utilizing the information.

The problem of assessing the value of soil test information has been addressed by Ryan and Perrin and by Colwell. The problem of assessing the value of weather information has been addressed by Byerlee and Anderson and by Doll. The value of soil classification information has been studied by Bie and Ulph and by Batavia. The procedure in the past has been to assume that separate response functions should be fitted for each soil class. But, given the production process specified in equation (1), soil class is but another variable in the production function. The question of whether to group sites into similar soil classes is identical to the question of whether to obtain information about the soil class, the variable C. In deciding whether to identify a soil before making a decision, one needs to ask whether the value of this information exceeds the costs of obtaining it.

There is yet another aspect of the site-information search problem. Just as there are alternative theoretical production models, there are also alternative soil classification models, alternative soil testing techniques, and alternative weather measurement models. As is the case for production models, each of these latter models must be considered as nothing more than approximations of reality, and the appropriate method of choosing among them is to calculate and compare their economic values. The value of a soil classification model, for example, will be the increment in expected payoff which can be realized by using that model rather than an alternative classification model. The alternative, of course, might be no classification model at all—pooling all sites together regardless of soil class.

In this section of the paper, two areas of application of the value of information are suggested, the question of the optimum number of experiments to conduct and the question of the amount of information to obtain about each site for which a decision must be made (soil classification, soil test, weather, etc.). Two areas of application of the value of a model are also suggested, the question of which response function model should be employed, and the question of which soil classification model (if any) should be employed.

Application to Corn Response in Brazil

The first question is which of two response models should be used, a generalized quadratic model or a "linear response and plateau" model as proposed by Waugh, Cate, and Nelson. The second question is related to the value of soil test information, and third the question is the value of two very simple soil classification schemes. The data used are from sixty-one experiments on the fertilizer response of corn conducted in the state of Minas Gerais from 1967 to 1969. (These data were gathered together by Robert Cate and the Brazilian Ministry of Agriculture.)

Procedures

Of the two response models, agricultural economists are familiar with the generalized quadratic response model. Yield is expressed as a quadratic function of fertilizer inputs and soil test. Interaction terms between these allow for differences in fertilizer response by soil test levels.

The linear response and plateau model (LRP) postulates a response curve exactly as the name implies. For any given nutrient, the nonfertilized yield is termed the threshold yield. As the level of this nutrient is increased, yield is assumed to increase from the threshold yield at a constant slope until a plateau is reached, at which time no further increases in yield can be obtained by additional doses of the nutrient. Of course, the level of the threshold yield, the slope of the response, and the height of the plateau will depend on the level of other nutrients applied. But the agronomists who proposed the model intended that the LRP for any one nutrient be estimated under conditions of a nonlimiting supply of the other major nutrients.

The LRP model is somewhat alien to agricultural economists, who tend to think of the world as having smooth curves rather than corners. On the other hand, it provides an approximation of a phenomenon that many agricultural economists have noted—that response curves often tend to be quite flat on top. The model allows only two rational levels of fertilizer, none at all or the amount required to reach the plateau (the nutrient "requirement"), depending on the price ratio and the slope of the linear response.

The LRP model has two potential virtues. First, it will likely result in lower fertilizer recommendations than curvilinear models applied to the same data. This is a virtue because experience has shown that curvilinear models generally result in recommendations higher than farmers are willing to undertake, presumably because of uncertainty and risk aversion. The second potential virtue is that it is very easily estimated by simple graphic methods. This can be an important consideration, given scarcity of statistical expertise, economic expertise, and computer facilities. Of course, the potential drawback of the model is that its inflexibility may result in serious specification error in estimating fertilizer response. If so, this should be detected when the value of this model is compared to that of the generalized quadratic model.

The formal classification of the soils on the sixty-one experimental sites was unknown at the time of this study, but several Brazilian soil scientists suggested that more homogeneous groupings of the sites would be helpful. As one alternative, they suggested grouping separately those sites with soil phosphorus in excess of ten parts per million from those with less. As a second alternative, they noted that the tests were conducted in two geographical regions of the state by different research groups. Geographical area, therefore, provided the second classification model. While these two simple approaches may not seem worthy of the title of soil classification models, they nonetheless serve the same purpose.

The procedures used to evaluate the response models, the classification models, and the soil test information, are as follows. Of the sixty-one experiments, thirty-one were randomly selected to provide data for the estimation of the response models. The remaining experiments were set aside to provide data for estimating the value of the models and soil test information. Five of the experiments in the estimation subset and two in the evaluation subset had incomplete soil test information, leaving twenty-six experiments for estimating the response models, and twenty-eight for evaluation.

Prices used in the analysis are \$0.045 per kilo of corn, \$0.30 per kilo of N, \$0.34 per kilo of P_2O_5 and \$0.14 per kilo of K_2O. These are the approximate prices prevailing in the area in late 1973.

A conceptual problem arises from the use of the data in this manner. Using the evaluation subset of the data, we wish to compare the

payoff from the fertilizer levels recommended by the alternative approaches. But these recommended levels will not, in general, be included among the experimental treatments in the evaluation subset. Hence, we are in the position of using each of the models to select the best from a finite set of fertilizer treatments, rather than the best of all possible fertilizer levels. Therefore, the procedure used is to employ the two response models to predict, a priori, the most profitable of the treatments used at each evaluation site. This is done both with and without soil test information and with and without soil classification schemes. Differences in average net returns from the treatments selected by the various approaches provide an estimate of the expected value of each approach.

The Value of the Response Models and of Soil Test Information

Table 1 shows the estimated coefficients of the quadratic model based on the pooled data from the twenty-six experiments. While a detailed discussion of the characteristics of this function are beyond the scope of this paper, the function does exhibit declining marginal product, except for potash for which there appeared to be no response. The interaction terms for applied nutrients and soil tests had the expected signs. No other functions were estimated.

The linear response and plateau (LRP) models were estimated graphically, using the procedures described by Waugh, Cate, and Nelson. In order to incorporate soil test in-

Table 3. Value of Soil Test Information and the Quadratic Model versus the Linear Response and Plateau Model

Production Model	Average Net Returns for Chosen Treatment with Soil Test Information[a]		Value of Soil Test Information
	Acquired	Not Acquired	
	($/ha)	($/ha)	($/ha)
Quadratic	177.49	171.33	+ 6.16
Linear response and plateau	178.81	147.89	+30.92
Value of the quadratic model	− 1.32	+ 23.44	

[a] Realized gross crop value minus fertilizer costs for that treatment chosen a priori, averaged over twenty-eight sites.

formation into the analysis, a separate response function was estimated for soil levels above and below "critical" soil test levels for P and K (determined according to Waugh, Cate, and Nelson). Soil pH was ignored, although it would be possible to estimate separate response functions for high and low pH groupings, as well. The estimated coefficients of the LRPs are shown in table 2. The estimation procedure revealed responses only for nitrogen (for all sites pooled), for phosphate with all sites pooled and for phosphate on soils testing less than ten parts per million of P. The phosphate "requirement" (the level required to reach the plateau) turned out to be the same for all sites pooled and for low phosphorus soils.

The data necessary to calculate the value of the models and the value of the soil test information are presented in table 3. The quadratic model was used in two ways. In one case the soil test reading from each of the twenty-eight sites was entered into the response function to predict which of the treatments would give the highest net returns. In the other case, the soil test average for the fifty-four sites was entered into the function, and the resulting equation was used for all sites.[4] The average net return (gross crop value minus fertilizer costs) on the twenty-eight sites in the first case was $177.49 per hectare. The average net return in the second case was $171.33, so that the difference of $6.16 per hectare is our estimate of the expected value of the soil test information, given that the quadratic response model is used. A t-test on the twenty-eight differences indicated that this average is significantly different from zero at the 0.01 level of significance.

If soil test information is available, the appropriate LRPs are the pooled nitrogen function described in table 2 and phosphate response curve 3 or 4, depending on the soil test. The average net returns of the treatments chosen by this approach were $178.81. This is $1.32 per hectare higher than for the use of the quadratic with soil test information. Thus, the best estimate of the value of LRP (with soil tests) compared to the quadratic (with soil tests) is $1.32 per hectare, although this average is not significantly different from zero, using a t-test on paired differences as a criterion. Still, it will be surprising to some that the LRP provides recommendations as valuable on the average to the farmers as those from the quadratic function.

When the LRP approach was used without soil tests, however, the results were significantly worse. The net returns averaged only $147.89 per hectare. This is $30.92 less than the LRP with soil test information, giving the soil test information a value of $30.92 per hectare. Regardless of whether ten parts per million is an appropriate division point, it is approximately correct to say that there is no phosphorus response on soils testing higher than this.

Also from this last value, $147.89, we can see that the value of the quadratic function is very high, $23.44 per hectare, if no soil test information is to be obtained.

The Value of Soil Classification Schemes

The two soil classification schemes have already been mentioned, classification by soil phosphorus level and by geographical region.

[4] The recommended levels of N and P_2O_5 from this equation are 128 kg and 42 kg per hectare for soils with an average soil test (pH = 5.28, soil P = 13.24 parts per million).

Table 4. Value of Two Soil Classification Models versus the Alternative of Pooling All Sites

Classification Model	Average Net Returns for Chosen Treatment[a] Using the Classification Model	Pooling All Sites	Value of the Classification Model
	($/ha)	($/ha)	($/ha)
Classification by soil test, P level (soils above & below 10 ppm)	154.24	177.49	−23.25
Classification by geographical region	168.32	177.49	− 9.17

[a] Realized gross crop value minus fertilizer costs for that treatment chosen a priori (utilizing soil test information and the quadratic model), averaged over twenty-eight sites.

These schemes were evaluated using the quadratic model and assuming that soil test information was available. The twenty-six "estimation" experiments and the twenty-eight "evaluation" experiments were each divided into two groups using the classification criteria. The quadratic function was fitted to each class of soils separately and predictions were made using the appropriate function for each of the twenty-eight evaluation experiments.

The results are shown in table 4. Both of the classification schemes turned out to have a negative value as compared to the alternative of no classification scheme at all—simply pooling all sites. The average net returns fell by $23.25 per hectare when the soil phosphorus classification scheme was used, and by $9.17 per hectare when the geographical classification scheme was used.

It may seem odd that pooling together "unhomogeneous" soils could result in better predictions (and presumably better recommendations) than would separating them into more homogeneous groups for analysis. The reason no doubt has to do with sample size. In fitting a single function to soils which may differ considerably, we introduce specification bias into our estimators, and we increase variability within the system. On the other hand, by pooling these various soils the sample size is increased, thereby reducing the variance of the estimators. Consequently, the estimators may be better in mean square error for any one homogeneous soil class, even though they are biased. In the case of these data, the beneficial effects of sample size have probably outweighed the negative effects of specification error.

Conclusions

This paper has suggested an approach to determine the value of alternative response models and has applied the approach to fertilizer response data for corn in Brazil. The results show that the linear response and plateau model, even though it is of the discontinuous type not favored by economists, can provide fertilizer recommendations as valuable to the farmer as those from a generalized quadratic model. This was only the case, however, when soil phosphorus test information was available.

One cannot generalize from this result on corn response in one state. Further comparison of these (and other) models on other data would first be necessary, and unfortunately the approach described here is both time- and data-consuming. But these particular results should serve to cast some doubt on the widespread (among economists) notion that fertilizer response should always be analyzed by fitting a smooth response surface.

Soil test information is quite valuable for fertilizing corn in this area, regardless of which response model is used to generate recommendations. One should be cautioned against multiplying the value estimated here by crop area to obtain the potential value of a soil-testing service. The value measured is compared with the alternative of knowing nothing about the piece of land. But farmers have a great deal of information about their land, and the value of this information may on the average be very close to that of the soil test information. If so, the net value of the soil test information would be small.

A final conclusion is that it is not necessarily desirable to group soils into homogeneous classes in order to make fertilizer recommendations. Quite the contrary, these results suggest that variability among experimental results is so great that the value of pooling experiments, in reducing standard errors of estimators, exceeds the costs imposed by introducing specification bias into the estimators.

The two classification schemes examined were crude ones. Much more sophisticated systems for classifying soils at various levels of aggregation are available. The value of these systems for making farmer recommendations would be an interesting topic for further empirical research.

A Risk-Programming Analysis of Forward Contracting with Credit Constraints

Peter J. Barry and David R. Willmann

A multiperiod risk-programming model is developed to evaluate forward contracting and other financial choices for farmers who are subject to market risks and external credit rationing. The model utilizes mean-variance analysis to derive sets of E-V efficient growth plans reflecting the influence of contracting on income stability, levels of credit, and income growth. A case farm is used to develop the model's decision elements and to survey the credit responses of lenders to contract choices. Model results indicate that the lenders' credit responses may modify the producer's contracting plans and his rate of income growth.

Key words: contracting, credit, firm growth, risk management, risk programming.

Increasing market risks together with rising farm debt have magnified potential losses of farmers' equity capital, hampered business planning and increased uncertainty in servicing debts and other financial obligations. Forward price contracting provides one response in risk management that removes the farmer's uncertainty of a future product price and assures greater certainty of loan repayability.[1] However, neither past research in contracting theory nor studies in financial management (e.g., Baker 1968a,b, Barry and Baker) have given systematic attention to interactions between contracting and credit.

In contracting theory, recent studies have used mean-variance analysis (Markowitz, Tobin) as a framework for evaluating optimal levels of contracting. McKinnon, for example, treated interactions between a producer's expected price risk and yield risk to determine a risk-minimizing level of contracting. Ward and Fletcher, Heifner, and Johnson used expected means and variances of returns in deriving combinations of cash positions and hedging in futures contracts that would minimize variance for a target level of returns.

These theoretical developments have focused primarily on short-run analyses for firms with fixed size, production organization, and financing programs. However, contract strategies may be modified if firm size and production organization are allowed to vary with credit becoming an effective constraint. Expanding credit becomes important and the producer may adapt his level of contracting to accommodate his lenders' preferences for greater certainty of loan repayment. Hence, it is important to establish procedures for evaluating the joint contribution of forward contracting to income stability, level of credit, and income growth.

Accordingly, the purpose of this paper is to demonstrate the development and structure of a multiperiod risk-programming model that is used to evaluate contract and other financial choices for producers who are subject to external credit rationing. Following sections describe the model's formulation, an empirical application, and a survey method used to measure credit responses of a sample of lenders to alternative levels of contracting.

The Risk-Programming Model

A multiperiod, quadratic program is used to model a firm's growth environment and to evaluate the effects of external credit rationing on optimal levels of contracting. The mathematical model is outlined below while its

Technical Article No. 11736 of the Texas Agricultural Experiment Station.

[1] Forward contracting generally specifies a price and time of delivery for either full production or a specified volume of production outside of an organized futures market. The empirical application in this study is concerned solely with contracting specified quantities of production.

more detailed features are discussed in the empirical application:[2]

$$\max U = \lambda CX - X'DX,$$

subject to

$$AX \leq B$$
$$X \geq 0,$$

where U = the value of the objective function, X = a column vector of activity levels defined over the respective time periods reflecting the firm's financial, marketing, and production choices, C = a row vector of gross margins and fixed costs defined as time-discounted values over the respective time periods, D = the variance-covariance matrix, with entries on open-market and contract sale activities defined as time-discounted values over the respective time periods, B = a column vector of the firm's resource levels and other constraints defined over the respective time periods, A = a matrix of technical coefficients for activities and constraints defined over the respective time periods, and λ = a scalar to be varied parametrically from zero to unbounded.

The model's basic structure resembles that of other growth models (e.g., Barry and Baker, Baker 1968b, Vandeputte and Baker) cast in terms of multiperiod linear programming with the addition of risk information expressed as variances and covariances on selected activities in each period. The multiperiod quadratic program consists of one matrix with years represented by submatrices of technical coefficients along the main diagonal and off-diagonal elements representing transfers of assets, liabilities, and other interyear effects. The objective function represents the summation of each year's linear and nonlinear entries over all years in the planning period. Hence, these specifications provide for a model solution that is jointly optimal over these years.

The linear portion of the objective function for each year is comprised of time-discounted expected values for gross margins on product sale activities, interest charges on debt, and depreciation charged against acquiring depreciable resources. The nonlinear portion for each year reflects time-discounted variances and covariances on gross margins of open market and contract sales—the major sources of risk to be evaluated. Interyear covariances are assumed to be zero.

The multiperiod quadratic program derives an efficient E-V solution, called a growth plan, that minimizes variance for a given net present value of income.[3] The E-V efficient growth plan prescribes production, investment, and market plans for each year in the planning period. Parametric variation of λ yields a set or frontier of E-V efficient growth plans. The last solution in the efficient set yielding maximum net present value of income from available resources is equivalent to the solution of a multiperiod linear program that differs only in the absence of the variance data.

Expected variabilities of yields and prices for resources and products are assumed to be reflected solely in objective function values for variances and covariances of gross margins on product sale activities in each year (Hazell, Rae). Constraint coefficients used to transfer assets and financial obligations from year to year are based on expected values for these respective activities and resource levels budgeted in the model. Thus, the model is designed to provide the decision maker with a set of a priori growth plans that organize the business to accept alternative combinations of risk and returns valued over the planning period. The decision maker must then choose the plan that best satisfies his preferences toward risk and returns.

An Empirical Application

A representative case farm for the Southern Blacklands of Texas is used both to develop the decision elements of the risk-programming model and to survey the credit responses of lenders to contract choices. The model's decision variables in each year include choices in producing cotton and sorghum; investing in land-machinery complements; short-term, intermediate, and long-term financing; consumption-taxation, and choices in market contracting—all in accord with choices faced by a representative producer in the Texas Blacklands. Annual and seasonal constraints include resource limits on land, machinery,

[2] Parametric quadratic programming can be formulated in several ways. This formulation follows that of Hadley and Sharpe with an algorithm programmed for computation by Cutler and Pass.

[3] Critics (Borch, Feldstein) of the mean-variance approach contend that it is only applicable if a manager's utility function is quadratic, reflecting preferences toward mean and variance of expected returns, or if he regards uncertain outcomes as normally distributed. Nonetheless, mean-variance analysis was judged suitable in this study for testing the response of contract strategies and income growth to external credit rationing.

Table 1. Production, Contract, and Financial Components for Year One of the Quadratic Programming Model

	Produce for		Contract Choices				Purchase Land-Machinery	Borrow	Consume and Tax	Cash-Transfer		Relation	Constraint Level
	Market Sale	Contract Sale	Total	Two-Thirds	One-Third	None							
Constraint	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8	X_9	X_{10}	X_{11}		
Income	C	C					$-C$	$-C$				=	max
Period 1													
Beginning cash	A	A						-1	A	1		≤	B
Ending cash	$-A$	$-A$						$1 + i$	A	-1	1	≤	0
Credit			$-3A$	$-3A$	$-3A$	$-3A$	A	A				≤	B
Market sale	-1		0	1	2	3						=	0
Contract sale		-1	3	2	1	0						=	0
Land-machinery	A	A					$-A$					≤	B
Consume	C	C					$-C$	$-C$	1			=	0
Period 2													
Beginning cash											-1	≤	0
Ending cash							A					≤	0
Credit							$\pm A$					≤	B
Land-machinery							$-A$					≤	B
Consume							$-C$					=	0

cash, credit, and requirements for consumption and taxation. Market requirements force production to be sold through one or more of the contract choices. Table 1 summarizes the linear portion of the model's structure for the first year and the transfer effects in the following year. Coefficients requiring empirical observation are defined in letter notation. Adding the variance-covariance data (table 2) on the market (X_1) and contract (X_2) sale activities in each year provides the quadratic formulation.

Specification of Financial Components

Growth in income-generating capacity occurs by acquiring additional resource capacities. Land-machinery investments add to resource capacities in the purchase year and in subsequent years, require loan financing, and reduce annual income to the extent of annual depreciation. Intermediate and long-term loans provide financing for investments. Credit is reduced by loan financing in the purchase year and is further modified in following years as asset equity is increased by debt repayments and by the appreciation and depreciation of asset values. Debt servicing requires principal and interest payments at specified time intervals with interest reducing annual income.

Short-term borrowing uses non–real estate credit to supplement cash flow through the year, requires payment at year end, and reduces income to the extent of interest paid. Cash activities transfer surplus cash through the year and to the following year. Family consumption and taxes are specified respectively by a declining marginal propensity to consume and a progressive tax rate structure (Vandeputte and Baker).

Non–real estate credit generated by income expected from product sales, including lenders' responses to contracting, is reflected in constraint coefficients for contract choice activities. Non–real estate credit provided by

Table 2. Variance-Covariance Matrix for Cotton and Sorghum Sales

	Market Sale Cotton (MSC)	Contract Sale Cotton (CSC)	Market Sale Sorghum (MSS)	Contract Sale Sorghum (CSS)
MSC	3,672	2,603	2,047	1,942
CSC	2,603	2,796	1,836	1,742
MSS	2,047	1,836	1,855	1,465
CSS	1,942	1,742	1,465	1,545

machine and other non–real estate collateral is reflected in right-hand-side values and in constraint coefficients for investment-financing activities. Real estate credit available to finance land purchases is specified separately.[4]

Specification of Production, Sale, and Risk Components

Production and sale of cotton and sorghum provide the major sources of risk and returns. Production uses land and beginning cash for growing crops, generates ending cash and net income, and requires open market and/or contract sale. Forward contracting is assumed to reduce both the level and variability of a producer's expected product prices. Reductions in price expectations reflect costs of contracting including the expectations of a price premium by forward buyers or speculators as reward for their acceptance of greater risk. To reflect lower price expectations, expected open market prices on each crop were set 10% above their contract prices in deriving expected gross margins for market and contract sales.[5]

Contracting prior to the harvest season was also expected to remove the producer's risk of seasonal price variation. Hence, variance-covariance entries on contract sale activities (X_2) reflect estimates of total variability of gross margins less the portion attributed to seasonal price variation. Entries on market sale activities (X_1) reflect estimates of total variability of gross margins.

Annual variances and covariances for gross margins of cotton and sorghum were derived from time-series observations of farm-level yields and prices. Weekly prices during harvest seasons were collected over the 1964–73 period. Annual yields were collected using farm-level data from a university farm in the study area. Estimates of variable production costs were obtained from secondary sources and deducted from the product of weekly prices and annual yields to provide weekly or seasonal time series of estimated gross margins.

Estimates of variability derived from these time series reflected jointly the effects of annual yield and price variation, seasonal (weekly) price variation and other random factors. No significant trends in annual gross margins were measured for these data sets over the period of observation. Estimates of seasonal price variation were obtained by averaging annual estimates of seasonal price variation over the entire time series and also by deriving seasonal measures of more recent years that were less influenced by government programs of price support and supply management. Model results reported here are based on the assumption that contracting will remove seasonal price variation as measured over the 1972–73 time period. For this time period, seasonal price variation comprised 23.8% and 16.7% of total variability in gross margins for cotton and sorghum, respectively. The estimated variance-covariance matrix is given in table 2.

Specification of Contract-Credit Components

Activities X_1 through X_6 (table 1) indicate the method of specifying interactions among production, contract choices, and credit. Four contract choices are specified: X_3 total contracting; X_4 contracting two-thirds of expected production; X_5 contracting one-third of expected production; and X_6 no contracting. The number of contract choices in the model corresponds to the number of contract choices evaluated in the lender survey.

Coefficients in the credit row reflect the rates at which credit is generated by the respective levels of contracting. The specification of coefficients in market and contract constraints for produce-sale and contract-choice activities together with zero level requirements assures that one or more contract choices will enter the solution at levels totaling one-third of levels in the production activi-

[4] Initial constraints include 275 acres of cropland valued at $450 per acre and appreciating at an annual rate of 8%. Each acre of purchased land is comprised of 0.8 acre of cropland and 0.2 acre of rangeland. Machinery investments of $60 per acre of purchased land are also required. Objective function values were discounted at an 8% rate to determine present values. Cost and return data for crops were developed from extension service budgets. Additional detail on model specifications is available from the authors.

[5] The very assumption of lower price expectations on contract sales has a greater potential impact on model results than does the exact magnitude of the reduction. Open market sales are then more profitable and, when credit effects are ignored, will tend to dominate the higher income solutions. Hence, the 10% margin is arbitrarily selected to reflect costs of contracting, including an expected risk premium. Most studies of price relations in forward sales have treated expected cash and futures prices in commodity futures markets (Gray and Rutledge). The implications for existence and size of risk premiums appear mixed, ranging from theoretical arguments supporting positive returns for the speculative function of risk bearing to empirical studies indicating little or no evidence of risk premiums. In this study, we assume that the market firm or speculator accepting a portion of the farmer's risk through the forward contract does expect to receive a premium for carrying the greater risk.

ties.[6] For no contracting, X_6 enters the solution at level ⅓ X_1. For one-third contracting, X_5 will enter the solution at level ⅓ $(X_1 + X_2)$ with X_1 double the level of X_2. Contracting one-half the crop could occur from a combination of contract activities yielding equal levels of X_1 and X_2. Other levels of contracting could occur in a similar manner.

The level of contracting in each E-V efficient solution depends jointly on the target level of income in the growth plan and its credit requirements, on the need for variance minimization, and on the relative rates of credit generation in the credit rows. If lenders do not discriminate among contract choices in their credit responses, contracting levels would depend solely on the price and variance effects associated with contracting. Moreover, as higher levels of income are sought by increasing λ, contracting should become less favorable relative to open market sales due to its lower price expectations.

When lenders do discriminate among contract choices in their credit responses, results depend on the value of credit in the solution. At low levels of income where credit is not constraining, contracting levels will again depend solely on price and variance effects. However, as higher levels of income are sought by increasing λ, there will be a tendency for contract levels with higher rates of credit generation to enter the solution in early years of the planning period to provide financing for greater growth.

Some caution is needed for interpreting levels of contracting (e.g., one-half the crop) that differ from those choices specified in the model. Since rates of credit generation for each choice are based on lender responses to those respective levels of contracting, a model solution indicating combinations of contract choice activities would in effect be averaging the credit responses given by lenders for other levels of contracting. When these levels of contracting occur, one must accept the assumptions that lender responses are linear and continuous between the levels specified in the model.

Measuring Credit Responses to Contracting

The basis for expecting lenders to discriminate among the borrower's contract choices rests on their preferences for greater certainty of loan repayment. Moreover, differences in contracting preferences between lender and borrower may arise from their differing risk positions in the loan transaction. The borrower participates directly in any gain or loss arising from the loan. The lender, however, is restricted to the returns, interest and principal, established in the debt contract. He only indirectly benefits from profits through the borrower's growth in financing needs over time. In addition, the lender's prior claims on the borrower's expected income and assets pledged to secure the loan request increase the borrower's financial risk.

Measures of credit responses to contracting were obtained from a sample of bankers and production credit associations who evaluated a case loan request with the interviewer simulating the manager of the representative cotton-sorghum farm. The simulated borrowing method has proved useful in prior research as a method of estimating a firm's total credit and evaluating lender responses to various managerial choices in a firm's financial and production organization (Baker 1968a, p. 507, 1968b, p. 1566). It provides a realistic setting for the lenders' credit evaluation and permits the interviewer to more directly control the variation of factors used to elicit the lenders' responses.

Banks included in the study were selected randomly from the study area. During the survey, some banks were deleted without replacement because of either inactivity in agricultural lending, lack of familiarity with contracting, or inability to provide a definitive credit response. Hence, credit responses were obtained from eight cooperating lenders who make agricultural loans and have some familiarity with contracting. While the sample is small and somewhat restricted in scope, it likely offers a representative profile of primary lending sources available to the case farm.

The case loan request included financing needed for operating expenses, debt servicing, and new capital investments. Loan documentation included three years of historical balance sheets, income statements, and flows of funds—accounts demonstrating the farmer's management and business performance. To test responses to contracting, projected cash flows in the loan request were budgeted under the four forward contracting alternatives described earlier. The loan request was set high enough to anticipate the lender's rejection and designed for deletion of individual capital

[6] This specification of coefficients in market and contract constraints requires that per acre rates of credit generation be multiplied by a factor of three when introduced in the model. The factor will vary with the number of contract choices in the model.

Table 3. Results of Lender Survey for Alternative Levels of Contracting

	Proportion of Crops under Contract			
	Total	Two-thirds	One-third	None
1. Operating loan request	54,460	54,460	54,460	54,460
2. Capital loan request	40,350	40,350	40,350	40,350
3. Total loan request (1 + 2)	94,810	94,810	94,810	94,810
4. Average loan granted	74,745	87,593	83,866	77,168
5. Asset credit	50,647	50,647	50,647	50,647
6. Crop credit (4 − 5)	24,098	36,946	33,219	26,521
7. Cotton credit per acre	54	82	74	59
8. Sorghum credit per acre	36	55	49	39

items until loan approval was obtained. Lenders were asked to designate their preferred level of contracting together with its loan limit and then indicate maximum loan limits for each of the other levels of contracting.[7]

Table 3 reports the size of the loan request (line 3) and the average of the lenders' loan limits (line 4) for each level of contracting. The loan limits are expressed in total dollars and in dollars per crop acre. To utilize the loan limits in the risk-programming model, coefficients of credit generated per crop acre were derived by deducting credit of $50,647 assumed to be generated by the borrower's equity in non–real estate assets available for loan security and allocating the remaining credit among cotton and sorghum according to their relative acreages and gross margins as budgeted in the loan request.[8] This allocation provides a more precise delineation of credit generated by income expected from crop sales.

Survey results indicate that larger loan limits are associated with contract choices X_4 and X_5, suggesting that an intermediate level of contracting is preferred to all or none. Two-thirds contracting exhibited higher credit than one-third contracting, and no contracting exhibited higher credit than total contracting. Analysis of variance indicated that differences among the per acre loan limits for the four contracts were statistically significant at the 2.5% level.[9] Lenders were not asked to justify their credit responses. Still they volunteered numerous observations and opinions that tended to be consistent with these credit responses.

Results Derived from the Risk-Programming Model

Efficient E-V frontiers are derived for a growth horizon of four years with model specifications on non–real estate credit that exclude and include the lenders' credit responses to contracting. The four year horizon was short enough to be computationally feasible for the quadratic program and long enough to observe time patterns of investment and contracting. Excluding the credit responses by specifying credit generation only at the rates for no contracting reflects nondiscrimination by lenders toward contract choices and provides a comparative basis for model solutions.

Tables 4 and 5 report acres purchased, total crop acres, contracting percentages, credit constraints, and objective function values of selected E-V solutions for the two model specifications.[10] The final solutions represent the income-maximizing plans at the peak of the E-V frontiers.

E-V frontiers are identical at low levels of income where credit is not constraining. Solutions in this range are generally characterized by relatively high levels of contracting, little or no land investment, and small diversification

[7] Additional contract levels (e.g., one-fourth or one-half of crop) could have been specified; however, more numerous levels of contracting would severely tax the lender's capacity to evaluate the case loan request. Also, lenders could have been left free to choose any level of contracting. But, specifying the four choices provided a more precise means of quantifying credit responses for the risk-programming model.

[8] Rates of credit generation per acre of cotton were assumed to be 50% greater than those for grain sorghum to accord with a similar ratio of gross margins for the two crops. However, in the case loan, sorghum acreage (336 acres) was 50% greater than cotton acreage (224 acres). Thus, each crop is expected to provide one half of the firm's total gross margin. To allocate credit among each crop, total crop credit (table 3, line 6) was divided in half and then further divided by the respective crop acreage.

[9] The analysis of variance utilized a completely random design with the four contract choices serving as treatments and the eight lender responses to each contract choice serving as replications. An F-distribution was hypothesized for the sample statistic with 3 (numerator) and 28 (denominator) degrees of freedom.

[10] The quadratic program yielded forty E-V efficient solutions when credit responses were excluded and fifty-one solutions when they were included. Six of these solutions are reported for each model variation.

Table 4. Results of Quadratic Programming When Lenders' Credit Responses to Contracting Are Excluded from the Model

among cotton and sorghum with cotton dominating. However, for higher levels of income (beyond solution 2) credit becomes constraining and the lenders' credit responses cause the E-V frontier to shift right and reach a higher level of income. These solutions specialize in cotton and can be contrasted by level and timing of contracting and land investment.

For excluded credit responses (table 4), solutions higher on the E-V frontier exhibit successively lower percentages of contracted production with the decline beginning in early years of the planning period. Contract sales decline because of their lower income expectations. The decline is initiated in early years because discounting to derive present values of income and variance favors higher returns from open market sales in those early years. Acreage purchased increases through solution 4 and then declines somewhat in subsequent solutions reflecting income trade-offs between lower levels of acreage and higher proportions of open market sales. The final solution yielding maximum net present value of income of $206,350 with standard deviation of $80,208 contains no contracting.

When the discriminating credit responses of lenders are included in the model, higher contracting in earlier years of the planning periods together with rapid growth in the land base characterize solutions all along the E-V frontier. Moreover, the proportion of contract sales remains relatively high in all E-V efficient solutions, declining somewhat at higher points on the frontier. Even the income-maximizing solution contains relatively high levels of contracting. These results contrast directly with the decline in contracting initiated in early years of solutions obtained with nondiscriminated credit responses. The relatively higher proportion of contracting in early years of the planning period generates greater credit thereby expanding debt-servicing capacity for purchasing land and machinery. Larger purchases of land and machinery in turn provide for growth in present values of income from production over the entire period. In the income-maximizing solution, the additional credit provided by contracting increases the net present value of income to $271,966 with a standard deviation of $105,281.

Concluding Comments

This risk-programming model has been formulated to provide a general method of integrat-

ing the problem dimensions of time, uncertainty, and a firm's organizational detail in evaluating forward contracting under external credit rationing. The model's structure and data requirements can be readily adapted to study other specifications on objectives, contract and investment choices, income and variance expectations, and kinds of commodities. Including sequential opportunities for contracting through the growing season would be a useful extension. The effects on credit, risk, and income of hedging with futures contracts could also be compared with forward contracting. Storage activities could be added to evaluate the joint contribution of forward sales and buffer stocks to reducing variability of income (McKinnon). Moreover, the procedure for measuring lenders' credit responses can include other choices in risk management and can be applied to lending institutions and farms differing in size, capital structure, type, and location.

The empirical application has contained a set of specific model specifications with results largely determined by relative magnitudes of the lenders' credit responses, price and risk reduction effects for contracting, and the discount rate. The model's results for these specifications indicate that when credit is valuable, optimal growth plans will include contracting even for managers with little or no aversion to risk and even though profit possibilities based on expected market prices appear more favorable with open market sales. Hence, it is clear that research and counseling programs with agricultural producers and their lenders on the merits of contracting as a market instrument should include some treatment of the credit effects (Barry).

Notes

The Differential Impact of Food Inflation upon the Poor

Loraine Donaldson

The poor spend a larger percentage of their incomes on food, and thus food inflation affects the poor more than higher income groups. A price index for foods purchased by the poor based on data gathered in Atlanta, Georgia—a fairly representative metropolitan area—is presented. It suggests that the cost of living of the poor during recent periods has been differentially affected by a larger increase in the price of their weighted food market basket compared to the increase in the average consumer's food market basket. A measure is also given of the degree to which food stamps failed to maintain constant purchasing power in Atlanta because of the rapid price changes.

The Index

Donaldson and Strangways (1971) compiled a weighted food market basket for the poor based on a year's accounting records of purchases at a supermarket located in a low income area of Atlanta. The annual average family income in the predominately black area in 1969 was $3,500, and 81% of the families had incomes of $5,000 or below. The market basket for people with incomes somewhat above as well as below the poverty line is distinctly different from the market basket of the average consumer as measured by the Bureau of Labor Statistics (BLS). While the poor may purchase some of the same items as the average consumer, invariably such common items make up a different weight or percentage of total purchases. And the poor purchase many items, such as pigsfeet, fatback, hog jowls, and neckbones, as well as cheaper brands of groceries not included in food lists of the BLS, because thery are not bought by the average consumer.

Prices in 1969 form the base period. In compiling the index, 112 products were priced on the same day of the same week of each month for one year. All chains with outlets in the vicinity of lower income census tracts within the city were represented in the index. The index is not seasonally adjusted, nor is the Atlanta BLS index to which it is compared. Inasmuch as produce accounts for less than 10% of the total index, seasonality does not have a large impact. However, the meat index and the total index are influenced by the seasonality of pork items. To date, no other statistically reliable index of this type has been established for other geographical areas. While the index reflects purchasing patterns of a predominately black poverty situation, the relative weights given to types of categories of items and most of the items used in those weighted categories will represent the price inflation impact upon other nonblack poor.

The difference between what the poor paid for food in 1974 compared to 1969 and what the average consumer paid will be larger than indicated by the differences in the index. There are several reasons for this. First, the composite BLS index includes both chains and independent groceries. The index for Atlanta's poor is a composite index that includes only chain stores. Independent ghetto stores have increased prices more than chain stores as can be seen from indexes for specific stores (table 1). Closely connected to the fact that the index for the poor would be higher if independent grocery outlets were included is the fact that the poor are more likely to spend a larger percentage of their food budget at independent stores than the average consumer because of the location patterns of chains in Atlanta and the relative immobility of the poor (Donaldson and Strangways 1973, p. 64). Thus, independents would tend to be more heavily weighted in the composite index of Atlanta's poor than in the BLS index if exact data were available.

Second, the poor have limited substitution possibilities in their budget because they already buy in the relatively least expensive categories of dietary needs. The average family can switch among items, changing to those that have increased less, and can diminish its total consumption of food and/or eat less of more expensive categories of food, such as better cuts of meat, by substituting less expensive protein sources—without loss of dietary standards necessary for good health. The BLS index does not account for the substitution of this type that goes on during periods of rapid inflation.

Produce													
BLS (Atlanta)	132.1	136.4	139.4	146.4	148.2	162.0	161.5	156.3	147.7	147.0	146.5	149.4	149.4
Atlanta's poor[a]	135.0	146.7	144.5	151.3	138.6	155.9	147.4	159.4	148.1	143.5	148.7	154.3	135.4
(independent)		129.5[c]	136.1[d]	185.0[e]									
Meat, Poultry, Fish													
BLS (Atlanta)	149.6	151.0	158.2	154.7	148.0	143.0	139.4	139.7	147.9	154.6	154.6	154.6	150.1
Atlanta's poor[a]	159.7	160.8	163.6	163.6	154.3	146.4	139.9	144.8	149.1	152.1	151.4	153.0	156.7
(independent)		147.9[c]	172.2[d]	198.8[e]									

[a] Index includes prices for chain stores only. BLS index includes independents.
[b] Includes nonfood items—cigarettes, soap, toilet paper, etc., purchased at grocery stores by the poor, weighted according to their relative importance.
[c] Downtown without nonfood (area with high competition for meats, poultry, and fish).
[d] Techwood without nonfood (formerly A&P).
[e] Ashby-Simpson without nonfood.

Finally, the poor benefit less from specials. Specials are run on items likely to attract the typical consumer, not the poor. The average family is able to "stock up" on food offered as specials. The poor are much less able to travel to bargain stores, do not have enough money to buy ahead, and usually lack freezer space for storage.

Disparate Inflation Impact

The index for Atlanta's poor and the Atlanta BLS index, as well as a breakdown into indexes for meat, poultry and fish, produce, and groceries, are shown in table 1. Prices jumped by 50% from August 1969 to December 1973 for the poor and by 40% for the average consumer. The difference between the two indexes is measurable in both the groceries and meat-poultry-fish price categories. However, a year later, in November 1974, the difference in the indexes was traceable in much greater part to higher grocery prices for the poor, which were 86% above 1969 prices compared to 66% for the average consumer. For the twelve-month period, December 1973 through November 1974, the BLS index averaged 150.2, while the index for Atlanta's poor averaged 157.5. Thus, during this period, the poor paid 5% more for food than the average Atlanta consumer.

Foods that added the most to the groceries index rise between August 1969 and December 1973 were canned vegetables, lard, sugar, canned fish, milk, eggs, bread and packaged pound cake, macaroni, spaghetti, rice, and dried beans. The subsequent large rise in the groceries index to 194.3 in February 1975 from the December 1973 level of 147.9 was a pervasive upward movement fed in part by the sugar and oils shortages. Sugar alone is heavily weighted in the index for the poor, and the price of sugar also affected other heavily weighted items including syrup, jelly, vanilla wafers, pound cake, bottled soft drinks, and canned fruits and drinks. Other important contributors to the further index climb were canned vegetables, bread, relishes and dressings, lard, shortening, margarine, peanut butter, evaporated milk, corn meal, and grits. One heavily weighted grouping—macaroni, spaghetti, rice, and dried beans—declined substantially between the end of 1974 and February 1975. Produce contributed much less to the index rise than groceries and meat, poultry, and fish. The 1969 weight for produce is 8.67 in contrast to 56.73 for groceries and 34.57 for meat, poultry, and fish.

Between August 1969 and December 1973, all meats advanced in price with salt fatback, streak-of-lean, pigsfeet, pork neckbones, and oxtail recording the highest percentage rises. Further rises in hamburger, stew meat, ham, and fryers brought the meat index to its peak in February 1974. The decline of the meat, poultry, and fish index from

Table 2. Price Indexes for Individual Food Items (Aug. 1969 = 100)

Oxtails	206	218	206	169	169	167	148	123	142	158	166

[a] Represented by streak-of-lean, fatback, pigsfeet.

163.6 in February 1974 to 156.7 one year later is traceable to declines in beef, particularly oxtails and hamburger, and to a lesser degree, declines in ham and bologna. In contrast, the low for this index of 139.9 in June 1974 reflects seasonal variations in pork and a decline in chicken prices in addition to the decline in beef. Drops in pork prices (except for spareribs, which experienced increases) accounted for 52% of the price declines from February to June, and chicken and beef for 24% each. Chicken and pork prices account for the subsequent rise of the index.

Price movements in the meat, poultry, and fish index help to explain the movements of the price index for the poor relative to the Atlanta BLS index. Chicken has a weight twice as large in the index for the poor, pork three times as large, while the weight used for beef is a little less than half that used for the BLS index. Of course, the meat cuts priced in the beef and pork categories differ also.

The difficulty of the poor in substituting among the basics they buy is illustrated in table 2. Individual indexes for food items which carry a heavy weight in the market basket have increased most in price. At the same time, the substitution effect as the average consumer switches to less expensive items contributes to the rise in the index of the poor. In the case of the meat index, additional linkage effects led to higher price rises for cheaper cuts not within the substitution pattern of the average consumer as grocers rearranged profit margins on a joint product.

As prices on meat rose, average consumers switched to cheaper cuts of meat, increasing their purchase of pork relative to beef, although few switched to offal products such as pigs' ears, pigsfeet, chitterlings, fatback, jowls, etc. This led to increased margins for pork chops, hamburger, ham, and chuck roast, but reduced margins for higher priced rib roast. As consumer resistance stiffened in response to rising meat prices and a period of retail price controls was enacted, farm prices continued to rise and grocers felt pressures on meat profits. Since chains do not cater to the poor, the easiest items to increase in margin were the lowest volume, lowest priced meats, including offal products bought by the poor. Such items show the highest margin increases (table 3).[1] Profit margins on pork relative to beef widened even further than the data indicate since there is little wastage on pork compared to beef.

The substitution and profit margin effects upon meat prices help explain the difference between the twelve-month meat index averages of 149 for the BLS and 153 for the poor. As a result of rising carcass prices and pricing responses to the average consumer's buying patterns, there are no longer any "cheap" meats for sources of protein in the sense that offal pork products, fish, chicken wings, backs, etc. are all priced higher relative to more expensive meats and relative to the income level of the poor. Even such standby sources of protein as beans and peanut butter have risen significantly.

Differences in the cost-of-living impact between the poor and the average consumer are more pronounced than the index differences in price changes in the market baskets of the two groups. Recent data indicate the poor spend between 35% and 40% and even more of their income on food (USDA). Middle income families spend between 15% and 20% of their income (10.4% to 12.9% for food at home), the near poor between 23% and 27%, and the upper income families spend 10% or less on

[1] Some independent stores in the downtown area and one small chain kept their pork prices on cheaper items much lower relative to large chains than in 1969. Both the manager of an independent store and of the small chain indicated that while they were competing for the business of the poor with lower prices, these were not loss leaders and their pork margins were not below normal during this period.

Table 3. Retail Meat Margins and Relative Changes, 1969–74 (Markup over Wholesale Price as a % of Wholesale Price)

	Weight in Index of Poor (1969 survey)	Aug. 1969	Dec. 1973	Change 8/69–12/73	July 1974	Change 8/69–7/74
Beef (U.S. choice)	5.29

food, including food away from home. Based on 1960–61 quantity weights but allowing for price changes since that time, the BLS cost-of-living index for urban wage earners and clerical workers showed food at home represented 17.8% of all items in December 1973 and 18.3% in December 1974 in Atlanta.

For purposes of comparing the diminution in purchasing power resulting from food inflation, a range of 16%–22% is chosen to represent the food cost-of-living component of expenditures for an average family and 35%–40% for the poor, and it is assumed that all food is consumed at home. The percentage price rises in the indexes from table 1 are multiplied by the cost-of-living percentage ranges to give an estimate of the disparate impact of food inflation upon the poor (table 4). The contribution of food to the rise in the cost of living of the poor was approximately 26% between August 1969 and November 1974, fifteen percentage points more than its contribution to the average family's cost-of-living increase. One-fourth of the fifteen-point difference is traceable to higher rises in the food price index for the poor. This is a conservative estimate of the differential impact for the reasons given earlier. Some of the immobile poor, shopping at less competitive ghetto independent stores may have experienced a budgetary erosion three times that of the average consumer.

Food Stamps

The food stamp program has alleviated some of the distribution effects of higher food prices, although during the period covered, over half the lower income and poor who were eligible did not receive stamps. Stamp recipients above certain minimum income levels receive varying subsidies according to their adjusted income and family size. Those in the upper ranges of income eligibility recoup some if not all of the differential between their cost-of-living increase and the average consumer's.[2] Those

[2] For example, assume the only distributional effects stem from changes in food prices, and consider two families. An average family is assumed to have a monthly income of $1,000 and spend 20% on food; the low income family is assumed to have a $350 monthly income and spend 35% on food. As a result of higher food prices, the cost of base year food purchases for the average income family rises to $300, a cost-of-living increase of 10%, while the cost of the lower income family's food rises to $280, a 21% cost-of-living increase. For the lower income family to experience the same 10% cost-of-living impact as the average family, their expenditures on the $280 worth of food would have to be held to $225. Assume the food stamp allotment for the family considered here is $150—the amount available to a family of four in the second six months of 1974. If the eligible family was required to pay $95 for the stamps, receiving a $55 subsidy, there would be no adverse distributional effects upon the family as a result of the food inflation. A subsidy of $55 was possible in 1974 for a family making $500 a month so long as its allowable deductions in arriving at eligible adjusted income were large enough. (If there were no allowable deductions, the family would have paid $126 for the

Table 4. Food Inflation Cost-of-Living Impact

receiving the highest subsidies are the most heavily protected from inflation under the stamp program. But, stamp recipients have experienced variations in the purchasing power of the stamps, and this in turn affects the degree of protection from food inflation and its distribution effects.

The dollar allowance per family under the food stamp program during the period covered was based upon the U.S. Department of Agriculture's economy food plan and was adjusted semiannually, with a six-month lag, for changes in the cost of this food plan. Inasmuch as the economy budget is created by the USDA and is composed of a small grouping of items designed to cover at minimum cost certain basic food needs for families, it does not reflect the actual purchasing patterns of the poor. The data for Atlanta's poor show variations in prices as high as 3% monthly, up to 6.8% quarterly, and a six-month rise of 12% from June to November 1974. Food stamp allotments for a family of four increased from $142 per month during the first six months of 1974 to $150 during the second half, an increase of 5.6%; and the yearly adjustment from January 1974 to January 1975 was from $142 to $154 per month, an increase of 8.5%. Thus, during 1974, the poor's food inflation index outpaced the increase in food stamp value, and the purchasing power of the stamps during individual months and quarters varied considerably. The importance of the discrepancy for the very poor varies inversely with the adequacy of the allotment. What nutritional levels are achieved by poor families of varying size, and in various geographic regions with the current, nationally-uniform food stamp allowance is, as yet, an unanswered question.

stamp allotment.) In addition to the relative effect, it is likely that absolute income limitations would force the lower income family to change its food purchase patterns since, even with the $55 subsidy from food stamps, it would have to spend $50 more per month to maintain previous food purchase patterns. Of course, the complexities of the distribution effects reach out farther than changes in food prices.

Social Costs Caused by Errors in Agricultural Production Forecasts

J. Bruce Bullock

Considerable concern has been voiced recently about inaccurate forecasts of agricultural production by the Statistical Reporting Service (SRS), particularly with respect to livestock numbers. SRS forecasts are a major (but not the only) source of information and thus affect allocative decisions in U.S. agriculture. The accuracy of SRS forecasts would appear to be a valid area of concern. Increased accuracy of SRS estimates would require additional expenditures. Several questions need to be answered prior to committing funds for this purpose. What is the nature and magnitude of social costs generated by SRS forecast errors? Do all forecast errors generate social costs? Is the magnitude of these social costs dependent on the size of the forecast error?

The purpose of this note is to develop models that help provide answers to these questions. An inventory adjustment model is used to evaluate social costs generated by inventory changes in response to a SRS forecast. A production adjustment model is used to examine the social costs resulting from production changes generated by a forecast.[1] These models ignore other sources of forecast information and the updating of SRS reports. Thus, they overstate the social costs of SRS forecast errors, but the models illustrate the nature of such social costs. The assumptions of the models are not intended to reflect reality. Rather, they define the conditions necessary to isolate the impact of forecast errors while restricting the analysis to two-dimensional graphs. Linear supply and demand curves are used for simplicity. However, the conclusions are not limited to linear functions.

Inventory Adjustment Model

The inventory adjustment model examines a two-time-period situation where production cannot be altered in response to output forecasts. The source of social cost is an erroneous SRS forecast of period two production. Harvest occurs at the beginning of each period. Consumption is spread over both time periods. The forecast is released prior to period two harvest, but after all period two production decisions have been made. Total supplies available for consumption in period one are known with certainty at the time the SRS forecast is released. Information about demand curves in the respective periods and about storage costs is also known with certainty at the time of the forecast.

Inventory holders are assumed to make inventory decisions at the time the SRS forecast is released. Consumption for the remainder of period one and carry-over into period two are determined by the following condition, $P_1 = \hat{P}_2 - C$, where P_1 is the price in period one, $\hat{P}_2$ is the expected price in period two, and C is the per unit storage cost.

The inventory adjustment model is represented in figure 1. Market conditions are depicted at the time the forecast of period two production is made; D_1 and D_2 represent the demand curves in the respective time periods; S_1 represents the total supplies (including stocks) available in period one; Q_2 is the true production that will occur in period two, i.e., the production level that SRS is trying to forecast; ED_1 and ED_2 represent the excess demand curves in the respective periods. (The reader not familiar with the derivation and interpretation of excess demand curves should see Bressler and King, pp. 206–9.)

The demand curve for storage services is RA. It is found by subtracting ED_1 from ED_2 at alternative levels of storage; RA shows the prices that consumers are willing to pay for alternative quantities of storage services. The area under RA is a measure of the total social value of alternative levels of storage.

The marginal social costs of using the storage inputs to store alternative quantities of the product from period one to period two is represented by CJ. In addition, CJ can contain a discount factor to account for time preferences of consumers. The area under CJ represents the total social costs of alternative levels of storage.

With perfect information (i.e., an accurate forecast) the optimal level of storage is defined by the intersection of CJ and RA. This equates the marginal social value of storage services with the marginal social cost of storage services. Thus, with a perfect forecast, OH units would be stored from period one to period two and $OM = (OS_1 - OH)$ units would be consumed in period one at a price of

J. Bruce Bullock is an associate professor in the Department of Economics and Business at North Carolina State University.

Journal series paper 4794, North Carolina Agricultural Experiment Station, Raleigh.

[1] These models examine the same situations considered by Hayami and Peterson. However, the Hayami-Peterson theoretical framework is incomplete. Thus, they have not appropriately identified the social costs due to forecast errors.

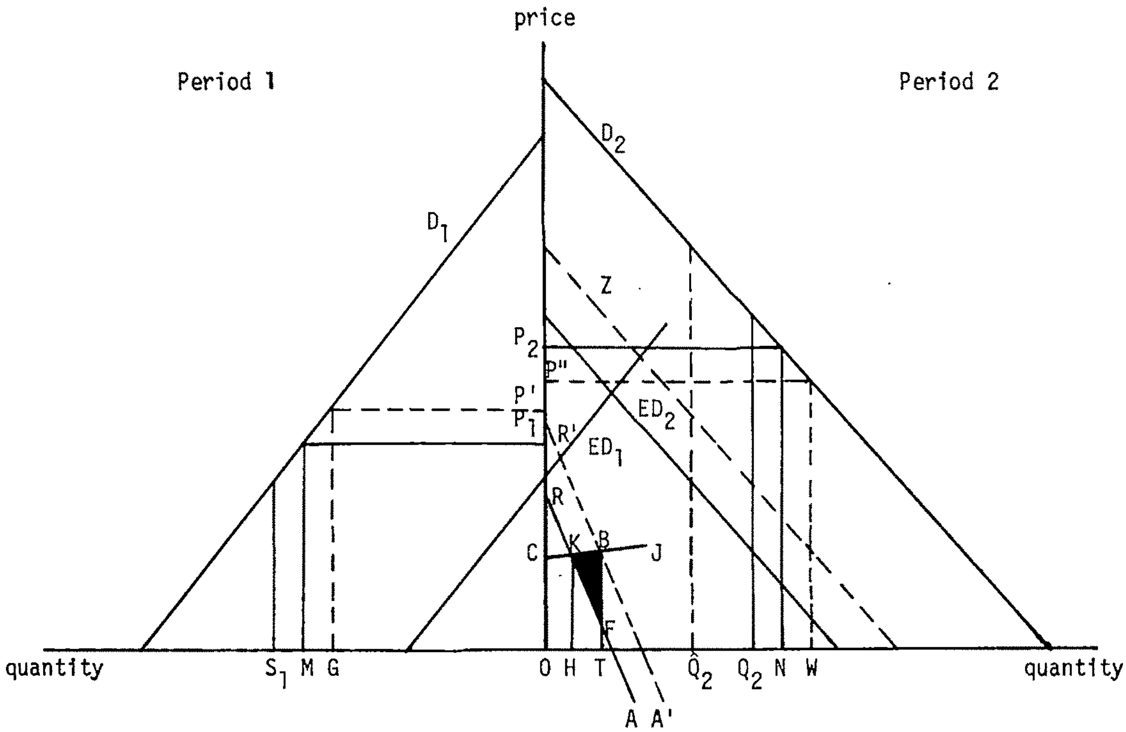

Figure 1. Inventory adjustment model, storage from period one to period two with perfect forecast

P_1. A total of $ON = (Q_2 + OH)$ units would be consumed in period two at a price of P_2. At equilibrium, the marginal value of storage $(P_2 - P_1)$ is equal to the marginal cost of storage (HK).

If SRS underforecasts the true production (i.e., $\hat{Q}_2 < Q_2$) and if the market uses $\hat{Q}_2$ as its estimate of period two production, then Z becomes the excess demand curve for period two. The excess demand curve for period one (ED_1) remains unchanged. The underforecast causes the demand for storage to shift to $R'A'$. Consequently, OT units would be stored from period one to period two, and OG units would be consumed in period one at price P'; $OW = (Q_2 + OT)$ units would be consumed in period two at price P''. The underforecast leads to more than the optimal amount of storage, since $(P'' - P')$ is less than the marginal costs of storage, TB.

The amount of excess storage generated by the erroneous forecast is measured by HT. The social value of this additional storage, $HKFT$, is less than the total social cost of the additional storage $HKBT$. Thus, the net social cost of the underforecast is measured by the triangle KBF.

The effect of underestimating period two production is to shift RA to the right resulting in more storage than is socially optimal. The magnitude of the social cost caused by an underforecast increases as the magnitude of the error increases. The social cost triangle is bounded above by CJ and below by RA; K is one point on all such triangles. The social cost triangle is bounded on the right by a vertical line drawn at the quantity stored as a result of the erroneous forecast.

Overforecasts of period two production cause RA to shift to the left and result in less storage than is socially optimal. The social cost triangle for an overforecast lies to the left of point K and is bounded by RA from above and CJ from below. The social cost of an overestimate of period two production has an upper limit of KCR. This limit is reached when the magnitude of the overforecast is large enough to shift the demand for storage (RA) downward sufficiently so that it no longer intersects CJ. Beyond this point, the social cost of forecast errors remain at KCR regardless of the magnitude of the overforecast.

This leads to two important observations. In those cases where actual supply and demand conditions are such that the intersection of CJ and RA occurs at very low levels of storage (i.e., there would be very little storage even with a perfect forecast), the social cost of an overforecast is small and will reach the upper limit at very low levels of overforecasting errors. Secondly, the social cost of an overforecast is zero regardless of the magnitude of the overforecast in those situations where there would be no storage from period one to period two given a perfect forecast (i.e., CJ and RA do not intersect). In situations represented by figure 1, all forecast errors generate social costs and there are direct social benefits from reducing the average level of SRS forecasting error.

Figure 2 illustrates the social cost of un-

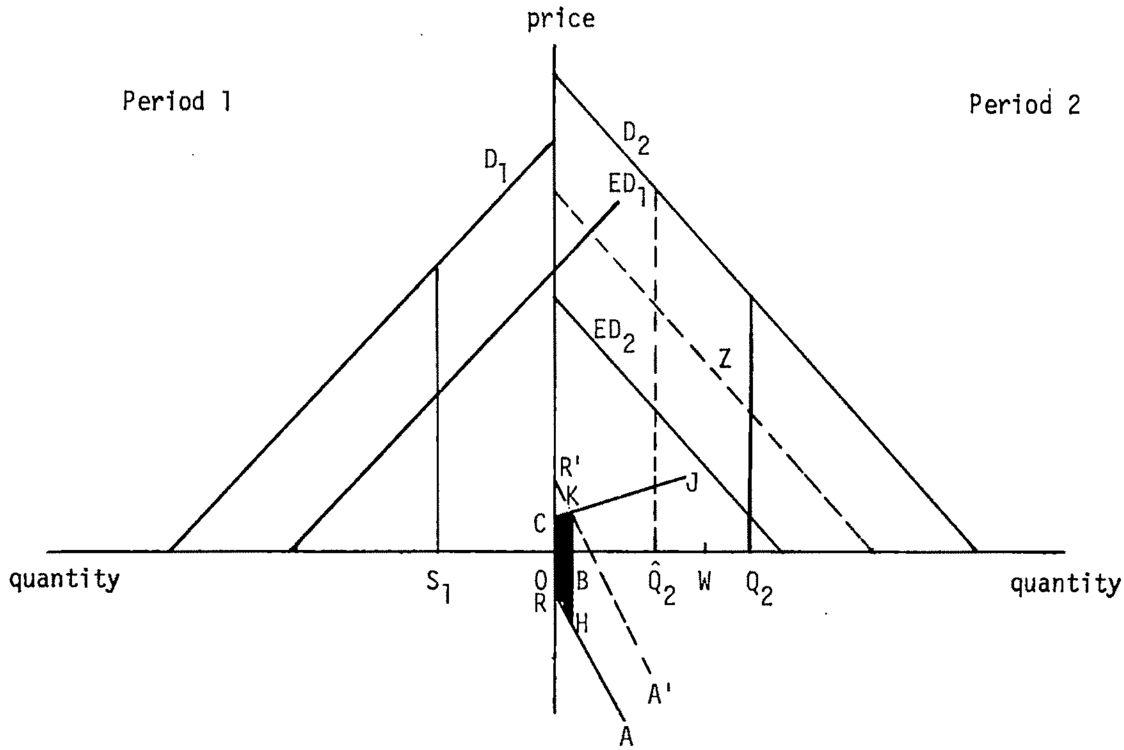

Figure 2. Inventory adjustment model, no storage from period one to period two with perfect forecast

derforecasts in situations where no storage would take place with a perfect forecast. The curves are labeled the same as in figure 1. With an accurate forecast, *RA* and *CJ* do not intersect leading to zero storage. The effect of an underforecast of period two production, $\hat{Q}_2$, is to shift *RA* upward. An error of this magnitude shifts *RA* to *R'A'* and leads to storage of *OB* units. This generates social costs measured by the trapezoid *CKHR* which is the sum of the social cost of storage *OCKB* and the negative social value of the storage *OBHR*. However, underforecast errors will generate social costs only when *RA* is shifted upward sufficiently to cause it to intersect *CJ*. Underforecasts between Q_2 and *W* will not generate social costs in the situation depicted by figure 2. The point *W* is the underforecast that would shift *RA'* upward to just intersect *CJ* at point *C*. Underforecasts between *W* and *O* will generate social costs as illustrated by *CKRH*. All forecasts greater than or equal to *W* will generate zero social costs. Thus, in situations represented by figure 2 there will be no direct social benefits from reducing the average level of SRS forecasting error unless the probability of a forecast being less than or equal to *W* is reduced.

The models developed above provide the following observations about the effects of forecast errors in cases where the inventory adjustment model is applicable. Not all forecast errors generate social costs. In many cases, the magnitude of the social cost of an erroneous forecast is independent of the magnitude of the forecast error beyond some minimum level of error. The social cost of a given forecast error is unique to the set of supply and demand conditions existing at the time of the forecast. Thus, it is not possible to categorically state that an X% forecast error will generate Y dollars of social costs. In general, the social cost of an X% overforecast is not symmetrical with the social cost of an X% underforecast. Thus the benefits to improved accuracy of SRS forecasts depend on how the frequency distribution of forecasts is changed.

Production Adjustment Model

This model applies to situations where producers have an opportunity to modify output in response to the SRS production forecast. The forecast is released sometime between the beginning of the normal production period and its scheduled termination. A single period where consumption equals production is considered. Forecast errors generate social costs through misallocation of resources in the production process. The magnitude of these social costs is determined by the prior production plans of producers and their subsequent modification of output in response to the SRS forecast.

The production adjustment model is depicted in figure 3; *DD* represents the demand curve for the product anticipated by producers; *SS* represents the supply curve at the beginning of the production

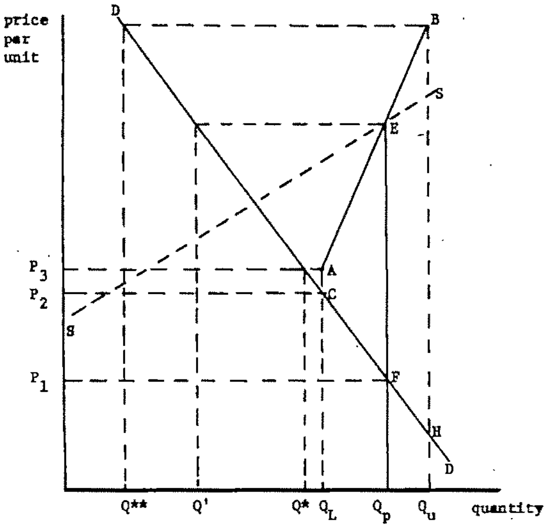

Figure 3. Production adjustment model with Q_L equal the socially optimal level of output

period. The initial intention of producers is to produce output Q_p. The necessary inputs have been committed to achieve this level of output; AB is the supply response curve of producers at the time the SRS forecast is released. Once the normal production process has begun, the ability (willingness) of producers to adjust output is restricted. At the time of the SRS forecast, Q_u is the maximum output that can be obtained by the designated harvest (slaughter) date and Q_L is the minimum production that will be placed on the market. The supply response curve becomes steeper and the distance between Q_u and Q_L diminishes as the length of time remaining in the production period is reduced. The slope of AB and the range between Q_u and Q_L also depend on the product in question.

Social costs measured by the area $CAEF$ are generated because of prior production decisions unless production plans are changed. (See Wallace for a discussion of the concept of social costs and socially optimal levels of production.) The social value (cost) of an SRS forecast arises from the reduction (expansion) of the area $CAEF$ due to modifications of output in response to the SRS forecast.

Figure 3 represents a situation where the lower bound on output is also the socially optimal level of output, given prior production decisions. In this situation, any forecast (regardless of its accuracy) that leads to a reduction in output up to Q_L will have positive social value. For example, if SRS accurately predicts Q_p as the level of output forthcoming, producers would anticipate a price of P_1 and reduce output to Q_L.[2] The price at the end of the period would be P_2. The social cost due to prior production plans has been eliminated as a result of the forecast. The social value of the forecast is measured by the area $CAEF$.

If SRS incorrectly predicted Q^* as the level of forthcoming output, producers would anticipate price P_3 and reduce output to Q_L. This erroneous forecast has the same social value as a perfect forecast, namely $CAEF$. Moreover, any forecast, F, such that $F > Q^*$ also has a positive social value equal to $CAEF$.

Any forecast in the interval $Q' < F < Q^*$ has a positive social value since the effect of any of these forecasts is to reduce output. However, these forecasts result in less than the maximum output reduction. Consequently, their social value is some portion of the area $CAEF$. A forecast $F = Q'$ has no effect on output level and thus has zero social cost.

Only those forecasts that cause an expansion in output have negative social value. Forecasts $0 \leq F \leq Q^{**}$ cause the maximum expansion of output. The social cost of any forecast in this range is measured by the area $FEBH$. Forecasts $Q^{**} < F < Q'$ also have negative social benefits measured by portions of $FEBH$ depending on the amount of output expansion generated.

Thus, in situations represented by figure 3, reduction of the average error of SRS forecasts will be certain to have direct social benefits only if the probability of obtaining forecasts less than or equal to Q' is reduced while at the same time changing the distribution of forecasts greater than Q' in such a way that the expected value of social benefits from forecasts $> Q'$ is not reduced. It is possible that a reduction in the average forecast error could also reduce the expected social value of the forecast.

Similar results are obtained from a graphical analysis where the demand curve lies to the right of the supply response curve AB. In this case, Q_u is the socially optimal level of output and any forecast (regardless of its accuracy) that leads to expanded output up to Q_u has positive social value.

Figure 4 illustrates the situation where the demand curve intersects AB, and thus the socially optimal level of output lies between Q_u and Q_L.[3] Forecasts $F \leq Q'$ cause output to be reduced to the lower bound Q_L. This generates social benefits equal to $GEF - GAC$. If $(Q_e - Q_L) > (Q_p - Q_e)$, the area GAC exceeds the area GEF and each of these erroneous forecasts generates social costs. However, these forecasts have positive social value if $(Q_e - Q_L) < (Q_p - Q_e)$ and have zero social cost if $(Q_e - Q_L) = (Q_p - Q_e)$.

[2] The measurement of forecast errors is thus impossible in cases where the production adjustment model is applicable. Prior production plans are not observable. In the above example, the true forecast error is zero. However, there is an observed forecast error of O_p (forecasted production) minus Q_L (observed production). If SRS had incorrectly arrived at Q_L as its estimate of Q_p, then the observed forecast error would be zero even though an incorrect estimate of Q_p had been made. There appears to be no definite relationship between actual and observed forecast errors.

[3] A special case of this situation is where DD and AB intersect at Q_p. In this case, all forecast errors regardless of their magnitude generate social costs.

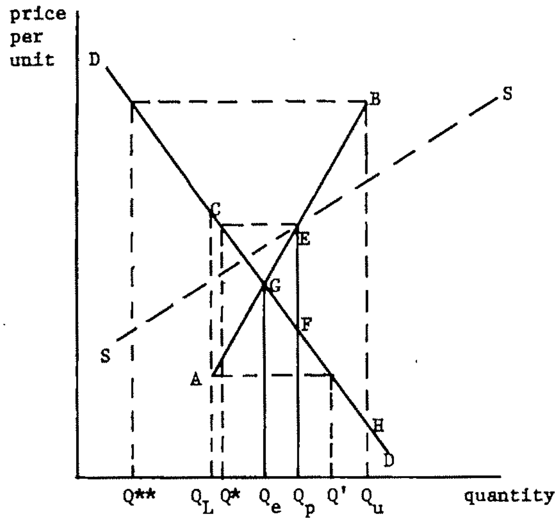

Figure 4. Production adjustment model with $Q_L < Q_e < Q_u$

Any forecast in the interval $Q_e < F < Q'$ has a social value of GEF minus some portion of GAC. The social value of some of the forecast in this interval is negative if $GAC > GEF$. A perfect forecast, $F = Q_p$ is contained in the interval $Q_e < F < Q'$. Thus, it is possible for a perfect forecast to have negative social value. The social value of forecasts in the interval $Q_e < F < Q'$ increases as F approaches Q_e. If $F = Q_e$, the social value of the forecast is maximum at GEF. Therefore, in situations represented by figure 4, if $Q_e \neq Q_p$, there exists a set of erroneous forecasts in the neighborhood of Q_e which have higher social value than a perfect forecast.

If $F = Q^*$, the forecast has zero social value since output is left unchanged. If $Q^* < F < Q_e$, the social value of the forecast is some portion of GEF. Forecasts in the interval $Q^{**} < F < Q^*$ cause output to be expanded and generate social costs measured by some portion of the area $EFHB$. All forecasts $F \leq Q^{**}$ have social costs equal to the area $EFHB$.

No general statement can be made about the direct social benefits from reducing the average level of SRS forecast errors in situations represented by figure 4. Many possibilities exist. It is clear, however, that the relative frequency of forecasts falling in certain intervals is the important determinant of the possible benefits, not just the average error. Reducing the average error is no guarantee that the expected social value of the forecast will be increased.

The models illustrated by figures 3 and 4 provide the following observations about the effects of SRS forecast errors in situations where the production adjustment model is applicable. Not all forecast errors generate social costs. In fact, there are many situations where even erroneous forecasts generate positive social value. In many situations only very large forecast errors generate negative social benefits. The magnitude of social costs (or benefits as the case may be) are often independent of the magnitude of the forecast error over a wide range of forecast errors. In some cases, erroneous forecasts have higher social benefits than accurate forecasts. In general, the social cost of a *X%* overforecast is not symmetrical with a X% underforecast. Thus, the benefits to improved accuracy of SRS forecasts depend on how the frequency distribution of forecasts is changed.

Conclusions

The models developed above illustrate the nature of social costs generated by production forecast errors in selected situations where the only source of imperfect information is the erroneous forecast. In general, accurate forecasts are preferable to inaccurate forecasts. However, large forecast errors are not sufficient grounds to argue for additional expenditures to improve the accuracy of SRS forecasts. In situations represented by the models, the sheer magnitude of the forecast error need not be of concern. The impact of an erroneous forecast depends on the set of supply and demand conditions existing at the time of the forecast. Moreover, reducing the average forecast error will not always generate social benefits. The key variable is how the frequency of forecasts has been changed in the process.

This note has not attempted to estimate the social payoff to improving the accuracy of SRS forecasts. This will require first, projections of the probability distribution of possible supply and demand conditions at the time of the forecast and secondly, estimates of the conditional frequency distributions of forecast errors (given the existing supply and demand situation) prior to and after the modification of SRS forecasting procedures. The expected social value of SRS forecasts prior to modifications could be compared with the expected value after modifications to obtain an estimate of the social benefits of the modifications. This does not appear to be a promising area of research, however, due to the complexities of obtaining the necessary estimates in a world characterized by many sources of uncertainty other than SRS forecast errors.

Futures Prices in Supply Analysis

Bruce L. Gardner

Empirical work on agricultural supply functions typically makes use of product prices from past time periods. This approach has the important advantage that it avoids the problems created by the simultaneous determination of supply and demand, since past prices are predetermined. But the approach has the important drawback that theory does not reveal exactly which past prices to use. The simplest procedure, use of last year's price, assumes farmers to be unduly naive in the formation of expectations. The more sophisticated lagged-price procedures following the work of Nerlove create econometric problems (Brandow, Nerlove 1958c, Griliches). Some are also liable to the charge of "theoretical ad-hockery" (Griliches, p. 42ff).

As an alternative approach to estimating supply elasticity, this paper is an attempt to exploit the theoretically well-grounded hypothesis that the price of a futures contract for next year's crop reflects the market's estimate of next year's cash price.[1] Since the appropriate price for supply analysis is the price expected by producers at the time when production decisions are being made, a futures price at this time is a good candidate for a directly observable measure of product price in supply analysis.

In the context of crop supply, there are several problems to be faced in the use of futures prices. First, "the market's" estimate as given by a futures price reflects the expectations of nonfarm speculators as well as crop producers, and it reflects directly the expectations only of those crop producers who themselves make futures transactions. Second, there is the issue of which futures contract is most appropriate. Third, at what date should the futures price be observed?

With respect to the first issue, the use of a futures price can be justified by the hypothesis of rational expectations as developed by John Muth. Under rational expectations, there is no reason for farmers to have different price expectations from futures speculators, nor for farmers who make no futures transactions to have expectations different from those who do. If the price expectations of those out of the futures market differ from the futures price, there is great incentive for them to enter. Thus, those out of the market likely have price expectations similar to the market price of futures.[2]

The second issue should cause no serious problem so long as the futures contract pertains to the new crop. Of course, even old-crop cash prices are influenced by expectations concerning the new crop. But the cash-futures basis changes from year to year and secularly as the cost of storage (which includes interest) changes. The present analysis uses the first futures price after the crop is in.

The third problem is most difficult because it is not clear exactly when the production decision is made. There may not be any preharvest date at which a farmer can be said to have made irrevocably his decision about planned output. Even after the crop is planted, planned output can be revised and actions taken accordingly in fertilization, pest control, and other practices, such as plowing under a crop or using it for forage. However, the main production decisions are the choices of acreage and techniques to follow in planting. This suggests taking as the expected price the futures price in the period immediately preceding the planting season.

When Nerlove (1956) introduced into agricultural supply analysis the fruitful innovation of the lagged dependent variable as an independent variable, he justified the procedure by an adaptive expectations model in which expected price is a distributed lag function of past prices. But as he notes (1956, p. 502n.) the resulting estimating equation is identical to that generated from a partial adjustment model in which expected price is simply last year's price.[3] The use of a futures price avoids this ambiguity. Under the maintained hypothesis that the futures

Paper No. 4860 of the Journal Series, North Carolina State University. The author acknowledges helpful comments from D. M. Hoover, T. E. Nichols, and R. A. Schrimper.

[1] The extent to which futures prices are unbiased point estimates of subsequent cash prices has been explored in a large theoretical and empirical literature, e.g., Dow, Working, Tomek and Gray, Telser. It seems fair to say that this literature does not indicate that futures prices for the major agricultural crops are biased. Telser concludes from his empirical analysis that, in fact, "the futures price can be considered as an unbiased prediction of the subsequent spot price" (p. 174).

[2] Hawtrey discusses the complications caused by people who have vague expectations or no expectations at all. He concludes that "the introduction of the expected price in any form, far from being simplification, is an additional complication" (p. 205), the implication being that we would be better off without the concept of "the market's" expected price. Nonetheless, in treating market supply, some such concept is necessary. If it turns out that many do not form expectations and act randomly or like robots, then the data should reveal it via insignificant response to "expected price."

[3] For a lucid explanation and comparison of adaptive expectations and partial adjustment models, see Nerlove (1958a) or Griliches (pp. 16–17).

price is the expected price, the coefficient of the lagged dependent variable arises from partial adjustment only. This fact is useful econometrically because the partial adjustment approach, unlike the adaptive expectations model, does not induce serial correlation when the supply equation errors are serially uncorrelated (Griliches, p. 17).

Although the use of a futures price in supply analysis seems basically plausible, it may be questioned for a number of reasons. Therefore, an appeal to concrete empirical problems is necessary to judge whether futures prices are useful in supply analysis. The remainder of this paper applies futures prices to the analysis of supply of soybeans (1950–74) and cotton (1911–33). These particular cases are chosen because there are good existing empirical studies with which to compare the results.

Supply of Soybeans, 1950–74

The futures price used for the analysis of soybean supply is the price of a January contract on the Chicago Board of Trade. The January contract yields a completely new-crop price. Because it is not certain at exactly what date the futures price should be observed and to help average out short-term price fluctuations, an average of futures-price observations is advantageous. However, to economize in data collecting, a simple average of only two prices is used. These are the closing price of the January position on the last Friday of the preceding April and on the last Friday of the preceding May.

The economic model used follows that of Heady and Rao. They explain soybean production as a function of the lagged (one year) price of soybeans, the lagged price of corn, lagged production, and a dummy variable denoting the presence of feed grain and acreage allotment programs for corn, wheat, and cotton. Table 1 shows estimated regression coefficients for a similar model on 1950–1974 data which allows comparison between lagged price and futures price results.

Equation (1) uses futures prices for soybeans and corn. For purposes of comparison, equation (2) presents lagged-price regressions. The directly calculated (short-run) elasticity of supply computed from equations (1) and (2) increases from 0.45 to 0.73 when futures prices replace lagged prices. The futures price also yields a lower standard error than lagged price.[4]

None of the equations contains an explicit policy variable. A couple of variables following Houck and Ryan were tried but were insignificant. The lagged-price equation substitutes the support price for lagged price in the one year (1961) when the support price was higher. The substitution makes no notable difference.

If adaptive expectations were the sole rationale for using the lagged dependent variable, then there would be no reason to include X_{t-1} in equation (1). However, the partial adjustment model predicts a smaller short-run than long-run supply response even when the expected price is included. Equation (3) drops X_{t-1}. The elasticity of supply with respect to futures price in equation (3) is less than even the short-run elasticity from equation (1). This result is consistent with the hypothesis that partial adjustment is important and that therefore X_{t-1} should be included along with the futures price. However, it is also consistent with Brandow's argument that including X_{t-1} may bias the estimated elasticity of supply upwards.

[4] Because corn and soybeans prices are highly correlated, it is possible to improve t-values on prices by using the ratio of soybeans to corn price as independent variables instead of the two prices separately. The ratio specification is used in Heady and Rao. On the 1950–74 data, the ratio of lagged prices yields a coefficient (with "t") of 249 (2.5), implying a short-run elasticity of supply of 0.69. The price ratio specification for futures prices yields a coefficient of 302 (3.6), implying a short-run supply elasticity of 0.83.

Table 1. Estimated Soybean Supply Functions, U.S., 1950–74

	Regression Coefficients (with t-ratios)[a]							Elasticity of Supply	
Equation	PS^*_t	PS_{t-1}	PC^*_t	PC_{t-1}	X_{t-1}	t	$\bar{R}^2$	SR	LR
(1)	219		−438		0.44	18.2	0.957	0.73	1.30
	(2.5)		(2.1)		(1.7)	(1.1)			
(2)		136		−315	0.43	19.6	0.948	0.45	0.79
		(1.3)		(1.3)	(1.5)	(1.1)			
(3)	184		−241			45.2	0.953	0.61	
	(2.1)		(1.3)			(9.3)			

[a] The dependent variable is U.S. soybean production in millions of bushels; PS_{t-1} and PC_{t-1} are the lagged season-average prices of corn and soybeans; PS^*_t and PC^*_t are the futures prices of soybeans and corn; PS^*_t is the price of January soybeans in April–May as discussed in the text; PC^*_t is the December corn futures price on the last Friday in April; X_{t-1} is the dependent variable lagged one year; t is time in years, 1950 = 1, 1951 = 2, etc.

Soybean Acreage Response

Although Heady and Rao explain output, it is more usual for agricultural supply analysis to explain acreage. This approach yields a factor-use equation and not a supply equation, and the "elasticity of supply" obtained is not an elasticity of supply in the usual sense. Nonetheless, acreage response functions are useful as an indicator of output intentions.[5] They are also suitable for the use of futures prices, especially when the futures prices are observed at planting time. Table 2 presents estimates of acreage response functions for soybeans using lagged prices and futures prices. Again, the futures price equation yields a larger point estimate of response elasticity than the lagged-price equation, although the apparent difference is not significant for the short-run elasticity.

Cotton Acreage Response, 1911–33

The cotton futures price used is the closing price of a December contract at the end of March.[6] The model is that of Nerlove (1958b) as modified by Tomek to make use of the data of Walsh. It does not include the price of an alternative crop, as the soybean model did, but deflates the cotton price by the U.S. Department of Agriculture index of prices paid by farmers. The use of the 1911–33 period is an interesting test case in that the use of futures markets by farmers was less widespread than in recent years. This puts the rational expectations hypothesis as a justification for using futures prices to a more severe test.

Regression coefficients for the model are presented in table 3. The coefficients and implied supply elasticities using the futures price are quite close to those obtained from the same model using the lagged price. The futures price and the lagged cash price seem to be good substitutes. In the cotton case, dropping the lagged dependent variable in equation (9) makes no difference in estimated response elasticity.

Conclusions

The use of futures prices seems a promising tool in supply analysis. In the soybeans and cotton equations, futures prices gave reasonable results and performed at least as well as Nerlovian lagged-price, lagged dependent variable specifications.

Futures prices have been applied in this paper only to crop supply, although the same basic idea could just as well be applied to livestock. Indeed, futures prices may be even more helpful in modeling the complex relationships of the livestock sector. For example, cow slaughter and placements on feed depend on near-term relative to longer-term price expectations. Futures prices for different positions give an observable indicator of near-term relative to far-term differences in price expectations.[7]

[5] A rigorous comparison of supply elasticity with acreage response elasticity can be made in the context of the model used in Floyd and in Richard Muth. Comparing Floyd's equation (7) for factor-use elasticity to Muth's equation (19) for supply elasticity, we have elasticity of acreage w.r.t. product price $= [e_a(e_b + \sigma)]/[\sigma + S_b e_a + S_a e_b]$ and elasticity of output w.r.t. product price $= [e_a e_b + \sigma(S_a e_a + S_b e_b)]/[\sigma + S_b e_a + S_a e_b]$, where S_a is the relative share of acreage in total cost, S_b is the relative share of all other inputs taken together, e_a and e_b are the own-price elasticities of supply of land and other inputs, respectively, and σ is the elasticity of substitution in production between land and other inputs. The elasticity of acreage with respect to product price will give an unbiased estimate of supply elasticity if land and other inputs are used in fixed proportions ($\sigma = 0$) or if the elasticity of supply of land is equal to that of all other inputs taken together ($e_a = e_b$). However, when $\sigma \neq 0$ and $e_a < e_b$, which is the likely real-world case, the acreage-response elasticity understates supply elasticity. The size of the bias depends on the magnitude of the parameters. To take an arbitrary example, if $\sigma = 0.5$, $e_a = 0.2$, $e_b = 1.0$, $S_a = 0.25$ and $S_b = 0.75$, the elasticity of product supply is 0.67 while the elasticity of acreage with respect to product price is 0.33.

[6] Two prices were averaged in order to smooth out single-day random price movements, the closing prices on Wednesday and Friday. These prices were chosen simply for convenience; the prices were taken from microfilms of the *New York Times*, and the Wednesday and Friday closing prices are both reported in Friday's paper. As it turns out, the correlation coefficient between the Wednesday and Friday price is 0.9987 in this sample.

[7] Leuthold (1974, 1975) finds that livestock futures prices are

Table 2. Soybean Acreage Response Functions, U.S., 1950–74

	Regression Coefficients (with t-ratios)[a]							Elasticity of Acreage

		(2.8)		(1.8)	(1.9)	(1.3)			
(6)	5.3		−1.6			1.70	0.977	0.45	
	(2.6)		(0.4)			(15.1)			

[a] The variables are the same as in table 1 except that the dependent variable is millions of acres of soybeans planted; A_{t-1} is the lagged dependent variable.

Table 3. Cotton Acreage Response Functions, U.S., 1911–33.

Equation	Regression Coefficients (with t-ratios)[a]				$\overline{R^2}$	Elasticity of Acreage	
	P_{t-1}	P^*_t	A_{t-1}	D		SR	LR
(7)	0.76		0.03	9.5	0.91	0.24	0.26
	(7.5)		(0.2)	(7.5)			
(8)		0.74	0.15	8.1	0.86	0.23	0.28
		(5.7)	(1.0)	(5.3)			
(9)		0.75		9.3	0.85	0.23	
		(5.8)		(10.7)			

[a] The dependent variable is millions of cotton acres in cultivation July 1; P_{t-1} is the previous season average price received by farmers. P^*_t is the price of December cotton futures at the end of March; P_{t-1} and P^*_t are deflated by the index of prices paid by farmers; D is zero in 1910–24 and 1 in 1925–33; (for a discussion of this variable, see Tomek [p. 109]); P_{t-1} and A are from Walsh (p. 368).

Futures prices can be valuable as an adjunct to and as a vehicle for evaluating lagged-price, lagged dependent variable models. Using futures price removes the main justification originally given by Nerlove for introducing the lagged dependent variable. The fact that substituting futures for lagged prices does not have a large impact on the coefficient of X_{t-1}—compare equations (1) and (2), (4) and (5), (7) and (8)—suggests that X_{t-1} is capturing something other than adaptive expectations of price. Nerlove himself indicates (1958c, p. 724n.) that he subsequently gave increased emphasis to the partial adjustment interpretation of the lagged dependent variable model. Nonetheless, the lack of evidence for an adaptive expectations effect being captured in X_{t-1} increases one's feeling that X_{t-1} may be picking up the effects of left out variables. More detailed work addressed specifically to such econometric problems would be necessary to draw any conclusions in this area.

[*Received June 1975; revision accepted September 1975.*]

poor estimates and systematically underestimate subsequent cash prices. This does not bode well for the use of futures prices in livestock supply studies. Nonetheless, the estimate, though poor, may still be "the market's" estimate, and the downward bias may indicate that expected prices have tended to be too low (instead of indicating that futures prices have been below expected prices).

Estimating Irrigation Response from Data on Unirrigated Crops

R. W. Palmer-Jones

In a paper in this *Journal*, Parvin suggests that, provided two conditions are met, the response of a crop to irrigation can be approximated from historical data on the unirrigated crop by assuming that irrigation will result in an increase in yield equal to the difference between actual yield and yield had "ideal" weather obtained. Ideal weather, as used by Parvin, is that which gave the maximum positive difference between estimated yield for "average" weather in a year and actual yield in that year.[1] The assumptions are that ideal weather occurred once during the data series and that irrigation has the same effect on yield as ideal weather. It is probably necessary to add a third assumption, namely, that no interaction exists between technological advance and response to weather and/or irrigation.

The second assumption is not valid in at least one case, and there are very good physiological and climatic reasons for supposing that the assumption will not hold in a wide range of circumstances. Parvin and Nelson make the point that all yield variability will not be eliminated by irrigation and the bias from using the assumption will be upward. Treating irrigation as rainfall will result in bias, but the direction will depend on the crop and environment.

Furthermore, while it enables use to be made of historical yield data, the method allows the evaluation of only those irrigation system operating policies—rules about how much water to apply to each area at each time with a given set of irrigation facilities—which enable maximum yields to be obtained. These policies, since they disregard costs, cannot be presumed always to be economically optimal. Consequently, the set of irrigation system operating policies and the system capacities required to implement them, which can be evaluated by the method, may not contain the economic optimum.

The assumption in question—that the effect of irrigation is the same as ideal weather—is similar to another assumption that appears quite frequently, explicitly or implicitly, namely that irrigation has the same effect as rainfall (Burt and Stauber, Carruthers and Donaldson). "Ideal" weather occurs in the year when the distribution of rainfall gives maximum yields; hence, if irrigation simulates this pattern, the same yield will result. This assumption is open to similar objections. Irrigation affects mainly soil moisture, while rainfall will be correlated with a wide range of other environmental variables such as temperature, humidity, radiation, and wind speed, all of which are known to affect plant growth and yield. In fact, irrigation will tend to be applied in conditions where these variables are at their opposite values to those prevailing in rainy conditions. For example, if temperatures under rainfed conditions are limiting plant growth, irrigation will tend to do better than the best rainfed yields, because in years when irrigation is necessary, temperatures in the absence of rainfall will tend to be higher. The opposite circumstances contain perhaps more dangers. Thus, if temperatures or humidities under rainfed conditions are at the upper limit of the response curve, then the higher temperatures and lower humidities associated with dry spells will limit yield response to irrigation to a lower level than may be expected with "ideal" weather. This latter situation is especially likely in the arid tropics and subtropics where much is hoped for from irrigation, but it is perhaps less probable in temperate regions and the humid tropics.

To be fair to many of the workers who have assumed that irrigation is equivalent to ideal weather, they have usually, but not always, made the assumption explicit.[2] Even so, it is worth emphasizing the importance of interactions among soil moisture, plant growth, and atmospheric environmental factors in determining growth and yield. Two examples from a study of the possibilities of

The author is grateful to the editor and two reviewers for comments which hopefully have improved the note. The work was financed by the Overseas Development Administration of the United Kingdom Government and the Tea Research Foundation of Central Africa in conjunction with Reading University.

[1] Ideal weather is defined by Parvin as those conditions which will result in maximum yields for the crops grown. As a result of the conclusions of this paper, one would also have to specify whether the crop was irrigated, since conditions for the area and time of year which give maximum yields under rainfed conditions might not give maximum yields under irrigated conditions.

[2] For example, Asopa, Guise, and Swanson make use of the methodology developed by Burt and Stauber in which rainfall and irrigation are aggregated, but they state neither the assumption, nor whether the data used for estimation came from irrigated or unirrigated yield data. If the latter, then multicollinearity between independent variables might be a significant source of error in estimated regression coefficients. For this reason, even the complex regression equation used, following Doll, and Burt and Stauber, might give biased results unless estimated using irrigation data.

irrigating tea in Malawi are given where estimates of response to irrigation using empirical yield-natural weather data have given highly misleading predictions. A somewhat more long-winded procedure to estimate response to irrigation from natural weather-yield relationships, which appears to be an improvement, is likely to have problems of statistical estimation.

The yield of tea may be related to the level of incoming energy, measured as evapo-transpiration, when soil moisture is not limiting (Laycock). Soil moisture was taken to be limiting whenever estimated evapo-transpiration in any ten-day period was less than rainfall in that period; in this case, the level of useable energy was put at the amount of rainfall. The annual sum (Etw) of whichever was less in each ten-day period, rainfall or evapo-transpiration, was correlated with annual yields and a highly significant coefficient found.[3] Laycock went on to suggest that irrigation would have the same effect as rainfall and that the effect of irrigation on yield might be predicted from his regression equations. An 80% increase in annual yield was indicated. Using later data, Shaxson found a similar result. Carruthers and Donaldson report a similar function for tea in Bangladesh.

Experience from irrigation experiments in Malawi, however, has failed to confirm the "Etw" hypothesis (Palmer-Jones). Yields from irrigated tea have nowhere in Malawi shown more than a 40% increase in annual yield, and it has been shown elsewhere (Palmer-Jones, p. 270) that the differences in yields between different irrigation treatments (including no irrigation) in different years is better explained by a partial regression of yield on Etw due to natural weather (Etwn) and on Etw due to irrigation, treated as a residual (Etwi), than by a regression of yield on total Etw. The two regressions gave determination coefficients (R^2) equal to 0.80 and 0.58, respectively.[4]

The regression coefficient of Etwi was less than one-sixth of that of Etwn implying that irrigation was considerably less effective than rainfall at increasing yields. This finding clearly illustrates the dangers of relying on natural weather-yield relationships for estimates of irrigation response.

The effect of irrigation on yields, as pointed out, is through its effects on soil moisture. Recently a study related yields in a number of years of unirrigated tea in Malawi to estimated soil moisture conditions at various times and suggested that irrigation response might be predicted from these measures (Willatt). Lal used a similar procedure in another place. The problem with this approach is the association between the estimated soil moisture conditions and the set of values of other environmental variables which will contribute to the determination of growth and yield. Thus, in unirrigated circumstances a low level of soil moisture deficit (the measure of soil moisture conditions employed by both Willatt and Lal) will have been associated with cooler, more humid atmospheric conditions which in the present circumstance can be expected to increase response to a given soil moisture regime. Consequently, a low level of soil moisture deficits under natural weather will be associated with a high level of yield. When the correlation between soil moisture deficit and atmospheric environmental factors is modified by irrigation, treatments which result in low levels of soil moisture deficit will usually be associated with hot, dry conditions which, in the present case, are unfavorable to growth and consequently produce low levels of yield regardless of soil moisture conditions.

Since the correlation of other environmental variables with rainfall is not perfect, there may still be some cool, humid years in which little rain falls and yields of irrigated tea may approach those which receive plenty of well-distributed rainfall. This appears to be the case in most years in Southern Tanzania (Carr) where tea is grown about 4,000 feet higher than the tea in Malawi. Again, analysis of the irrigation experiment mentioned above shows that the response to reduction in soil moisture deficits was generally smaller than predicted by Willatt's regressions by an amount which varied from year to year. This yearly variation appeared to depend on the values of atmospheric, environmental variables which could be measured by the number of days of low evaporation (less than 0.20 cm. per day); in the irrigation experiment these were independent of soil moisture conditions. The coefficient of this variable was significant and positively related to yield (Palmer-Jones). When most days had low evaporation, the response of tea was similar to that described by Willatt's function. Details of this work, which are not relevant to the points being made here, are given by Palmer-Jones.

Unfortunately, reliable data from unirrigated tea were not available to estimate the response function, including soil moisture conditions and the number of days of low evaporation. In any case, the estimation of such a function from only rainfed conditions might run into the problem of multicollinearity between independent variables, since in unirrigated conditions, the number of days of low evaporation would be correlated with soil moisture

---

[3]
$$Etw = \sum_{t=1}^{36} (M_t),$$

where

$$M_t = (\min E_t, R_t);$$

t are the ten-day periods in a year numbered from 1 to 36, $E_t = 0.85 \times$ Class "A" USWB evaporation pan in period t in inches—an estimate of actual evapo-transpiration, and R_t = rainfall in period t in inches.

[4] Further examination (Palmer-Jones) of the hypothesis suggested that there was in fact no correlation between annual yields and Etwn. The original result was due to variations in the periods over which yield and Etw were summed. Shaxson's result was due to pruning which artificially reduces yields and Etw one year in three. Grouping years by stage of prune resulted in nonsignificant correlation coefficients ($P > 0.05$). The significant partial regression coefficient of Etwn found by Palmer-Jones was due to the inclusion of years of prune.

conditions. Furthermore, yield will be affected by soil moisture conditions throughout the life of the plant and, consequently, independent variables for soil moisture at several points should be included. However, in rainfed conditions there will tend to be serial correlation among these variables in a given year; a large soil moisture deficit early in the season will be associated with larger deficits later.[5]

To summarize, the results of yield-weather studies of tea in Malawi suggest that irrigation will not generally have the same effect on yield as rainfall or "ideal" weather due to the different associations between rainfall and irrigation and atmospheric environmental variables which affect response to soil moisture conditions. Even the inclusion of independent variables to reflect the influence of these factors will not be without dangers when the estimation of regression coefficients is based on natural weather—yield data alone; this is due to the potential multicollinearity between atmospheric environmental variables and soil moisture conditions at any one time and serial correlation of, at least, soil moisture conditions.

A properly designed irrigation experiment would allow the effect on yield of different quantities of water applied, and hence the effect of different soil moisture conditions in each period in the irrigation season to be evaluated. By following each set of soil moisture conditions in one period by several different sets in the next period, the multicollinearity between variables and serial correlation of soil moisture conditions in different periods will be avoided.

[5] This serial correlation will also be apparent in some irrigation experiments where typically the same rule about when and how much irrigation water to apply is used through the irrigation season on a given plot. Thus, if the experiment compares irrigation at 3-inch deficits with irrigation at 1.5-inch deficits, final yield could be due to any of the deficits each of which will be correlated over time. A similar problem arises in experiments which irrigate at a constant volumetric soil moisture content. The solution is to apply different rules at different times (Palmer-Jones).

Uncertainty and the Choice of Tenure Arrangements: Some Hypotheses

Samuel P. S. Ho

Recently, in this *Journal,* Adams and Rask and Boxley discussed the problem of tenure arrangement, in particular the apparent misallocation of resources under share tenancy. Their analyses operate within a framework of certainty and do not explicitly consider many of the conditions of the lease contract that are subject to negotiation. However, to gain a more complete understanding of why differing tenure arrangements exist and the conditions under which parties to the lease prefer one arrangement over the others, a more realistic framework is required. This paper attempts to move in this direction by relaxing the assumption of certainty. As a first step, we investigate how differing tenure systems alter the risk to landowners and tenants. We then identify and investigate a few of the factors affecting the choice of tenure arrangement when uncertainty is an inherent factor.

Given certainty, landowners and tenants are presumably concerned solely with their income. But when uncertainty is introduced, both the level of income and its variability need to be considered. Uncertainties in farming are caused largely by the uncertainties of nature, changing technology and market conditions, factors that are beyond the control of, and often also the insurability by, individual farmers. In other words, a farm produces not a known income but a probability distribution of income. Given a probability distribution of income that can be produced from a piece of land, the probability distribution of the landowner's income and that of the tenant-peasant differ significantly when the land is operated under different tenure arrangements.

Assume that the net income from farming one unit of land, x, is a random variable with a distribution, $f(x)$.[1] Further assume that $f(x)$ can be fully described by its mean (μ_x) and variance (σ_x^2). Given $f(x)$, table 1 summarizes the means and variances of the landlord's income and those of the tenant when the land is operated under several common tenure arrangements.

Most of the results are familiar, so it is only necessary to briefly review them. Under the owner-operator system, the owner bears the risk of income variations.[2] Under the fixed rent arrangement, the landowner is assured of a fixed nominal income and the tenant bears all the risk.[3] Under the crop-share arrangement, the landlord and the tenant split the risk of income variations in proportion to their respective shares of income.[4]

The fixed rent contract with escape clause is perhaps less familiar than the other arrangements. The purpose of the escape clause is to permit the tenant to pay a reduced rent, βR ($0 \leq \beta \leq 1$), when farm income falls below some critical level, x^*.[5] Following are two sample escape clauses found in rental contracts concluded in China in the 1920s and 1930s. The first example is from a fixed rent contract with escape clause from Tsinghai province: ". . . the [aforementioned] rental rate is subject to adjustment according to local customs in a famine year" (China, pp. 54–55).

The second example is from a fixed rent contract with escape clause from Anhwei province: ". . . the landlord is invited to inspect the fields damaged by insects, flood, or drought, and rent is adjusted according to the extent of damage . . ." (Kuo and Hung, p. 62).

In the first example, x^* is defined as famine condition and β, the extent of rent reduction, is only stated as that determined by "local custom." The second sample escape clause is a more compli-

Samuel P. S. Ho is an associate professor of economics at the University of British Columbia.

The author is indebted to Ralph W. Huenemann, David Newbery, Thomas Wiens, and two anonymous referees for helpful comments.

[1] Net income is gross receipts from farming minus all costs except that of labor and land.

[2] Under the owner-operator system, the peasant bears no risk if it is assumed (as we do in table 1) that he can always find work as a hired laborer. However, once this unrealistic assumption is relaxed, then the peasant must bear the risk of not finding work, i.e., var(Y_t) is no longer zero.

[3] The assumption here is that land is the only input supplied by the landowner. This is, of course, only one of the many possible arrangements. Sometimes landowners also supply some variable inputs, e.g., the services of draft animals. In these cases, the landowners usually receive a larger cash rent but bear the risk of variation in input prices. Finally, unless the rent in prepaid, the landlord must bear the risk of rent default.

[4] For simplicity, we assume that output and production costs are shared in the same proportion. Often, this is not the case. If the tenant bears all the production costs, he necessarily also bears the risk of variations in production costs and only shares with the landowner the risk of variations in produce prices and yields. To take account of the many ways variable costs may be divided between landowners and tenants would complicate our analysis without yielding additional insights into the issues under examination.

[5] This type of asymmetric (in the sense that the landlord's rental income is reduced when farm income is low, but is not increased when farm income is high) escape clause is probably most common. But there is no reason why escape clauses cannot be symmetric.

Table 1. Means and Variances of Landlord's and Tenant's Income under Different Tenure Arrangements

Tenure System	Landowner		Tenant-Labor	
	$E(Y_l)$	$\text{Var}(Y_l)$	$E(Y_t)$	$\text{Var}(Y_t)$
Owner-operator				
$Y_l = x - W$ $Y_t = W$	$\mu_x - W$	σ_x^2	W	0
Fixed cash rent				
$Y_l = R$ $Y_t = x - R$	R	0	$\mu_x - R$	σ_x^2
Crop sharing				
$Y_l = rx$ $Y_t = (1 - r)x$	$r\mu_x$	$r^2 \sigma_x^2$	$(1 - r)\mu_x$	$(1 - r)^2\sigma_x^2$
Fixed rent with escape clause				
$Y_l = R,\ x^* < x$ $= \beta R,\ x \le x^*$ $Y_t = x - R,\ x^* < x$ $= x - \beta R,\ x \le x^*$ $0 \le \beta \le 1$	$R - (1 - \beta)R \int_{-\infty}^{x^*} f(x)dx.$	$\int_{-\infty}^{x^*}(\beta R - R^*)^2 f(x)dx$ $+ \int_{x^*}^{\infty}(R - R^*)^2 f(x)dx$	$\mu_x - R + (1 - \beta)R \int_{-\infty}^{x^*} f(x)dx$	$\sigma_x^2 + \int_{-\infty}^{x^*}(\beta R - R^*)^2 f(x)dx$ $+ \int_{x^*}^{\infty}(R - R^*)^2 f(x)dx$ $- 2R(1 - \beta) \int_{-\infty}^{x^*}(\mu_x - x)f(x)dx$

Note: Y_l is landlord's net income, Y_t is tenant's net income, R is cash rent per unit of land, W is wage, r is rental share, x is net income $(Y_t + Y_l)$, μ is mean, σ^2 is variance, and $R^* = R - (1 - \beta)R \int_{-\infty}^{x^*} f(x)dx$.

cated one since it suggests that there may be several β's, each governing a different range of output.

In effect, the escape clause specifies the conditions under which rent default is legally permissible and therefore it tends to increase the variability of the landlord's income, $\text{var}(Y_l)$, and to reduce the variability of the tenant's income, $\text{var}(Y_t)$. Given R, the expected value of the landlord's income is, of course, also reduced and that of the tenant increased. In general, other things being equal, the closer β is to zero and the higher x^* is, the lower would be the landlord's expected rental income and the higher would be the tenant's expected income. An increase in β has the effect of decreasing $\text{var}(Y_l)$ and increasing $\text{var}(Y_t)$. However, the effect on $\text{var}(Y_l)$ and $\text{var}(Y_t)$ of an increase in x^* is more difficult to predict since $\frac{\partial \text{var}(Y_l)}{\partial x^*}$ and $\frac{\partial \text{var}(Y_t)}{\partial x^*}$ may be either positive or negative.

Since the landowner's income and its variability, as well as those of the tenant, are significantly different under different forms of tenure arrangement, the choice of tenure arrangement clearly depends on the attitude toward risk, the variability in income, and the available trade-off between the level of income and its variability implicit in the various tenure arrangements.

One interesting case is when the peasant's attitude toward risk and therefore the choice of tenure arrangement may be strongly influenced by the position of his income (Y_t) relative to the following three income levels: the minimum level required for physical survival (Y_{mp}), the minimum social subsistence level (Y_{ms}), and the desired level (Y_d) (Miracle, pp. 295–300; Wharton, pp. 29–32). For a given environment, Y_{mp}, the level of income necessary to maintain life is constant; Y_{ms}, on the other hand, is a socially and culturally determined minimum. It is what the peasant's immediate society considers, at a given moment in time, to be the minimum acceptable level of income; Y_{ms} is at least equal to but usually higher than Y_{mp}. The extent to which Y_{ms} exceeds Y_{mp} depends on the average standards of living historically, as well as on other social and cultural factors. The higher the historical standards of living, the higher is Y_{ms}. Over time, as the average living standards rise, we would also expect Y_{ms} to rise, but with a lag; Y_d, the desired level of income, reflects the peasant's aspiration, and as such it is flexible over time and can be changed quickly. The relationship between these three levels of income is most likely $Y_{mp} \leq Y_{ms} \leq Y_d$. The peasant has the dual objective of attaining Y_d and remaining above both Y_{ms} and Y_{mp}. We would expect that the closer he is to Y_{ms} (or Y_{mp}), the greater is the weight given to the objective of remaining above it.

To illustrate, consider how a peasant's choice of rental contract might change as his relative income position is altered. Assume that he is faced with the choice of selecting between two rental contracts, one being a fixed-rent contract (f-r) with rent R and the other a crop-sharing contract (c-s) with rental share r. Further assume that the peasant, from his own experience or from historical records, knows the mean (μ_x) and standard deviation (σ_x) of x, the income from the farm in question. We shall argue that depending on how the peasant's expected income $E(Y_t)$ is related to Y_{mp}, Y_{ms}, and Y_d, his choice of tenure arrangement may be very different.

Figure 1 depicts the condition facing most peasants in an agriculture before the beginning of rapid progress. In such an economy, we would expect Y_{ms} to exceed Y_{mp} but by only a small margin; μ_x is likely to be at a level at which the peasant's expected income under either rental systems would be near Y_{ms}. In this situation, because he is not only very close to his social subsistence but also close to his physical subsistence, the peasant would have a strong aversion to any variability in his income. Thus, even though his expected income is lower under the share contract than under the fixed rent contract, $(E(Y_t)_{c-s} < E(Y_t)_{f-r})$, he would prefer the share contract for its lower variance and the lesser likelihood that his income would fall below Y_{mp}.[6]

In a commercialized and fairly well-developed agriculture, we would expect both Y_{ms} and Y_d to be substantially higher than Y_{mp}. Most importantly, μ_x is likely to be significantly higher than in the subsistence case, so that the tenant finds himself with an expected income, under either crop-sharing or fixed rent contract, sufficiently high that he is unlikely to fall below Y_{mp} or Y_{ms}. He is, therefore, less concerned with remaining above Y_{ms} than with achieving his desired level of income. Because his expected income is higher and because he has a greater chance of achieving Y_d under the fixed rent contract than under the share contract, he is likely to prefer the former.[7]

It is important to note that tenure arrangements may influence yield variations (or uncertainty) in the long run through their effect on land conservation. Ciriacy-Wantrup suggests that when tenants are responsible for conservation decisions, fixed rent may be undesirable from the standpoint of conservation, because during recessions the lower income of tenants tends to increase their time preference rates and lead to depletion [pp. 103–9, 155–57]. An easy remedy of this problem is to include in the lease contract a clause requiring the tenant to return the land in the same condition as he

[6] In figure 1 the income lines for the two tenure arrangements are positioned so that they intersect to the left of μ_x; thus at μ_x, the tenant's income from the fixed cash lease is greater than that from the share lease. This is likely since under crop sharing, landlords share the risk of farming and often also participate in farming decisions and consequently would receive a higher return. If the income lines intersect to the right of μ_x, then the share lease would be preferred by the tenant for its higher expected income as well as its lower variance.

[7] Again, we assume that the two income lines in this case, as in figure 1, intersect to the left of μ_x.

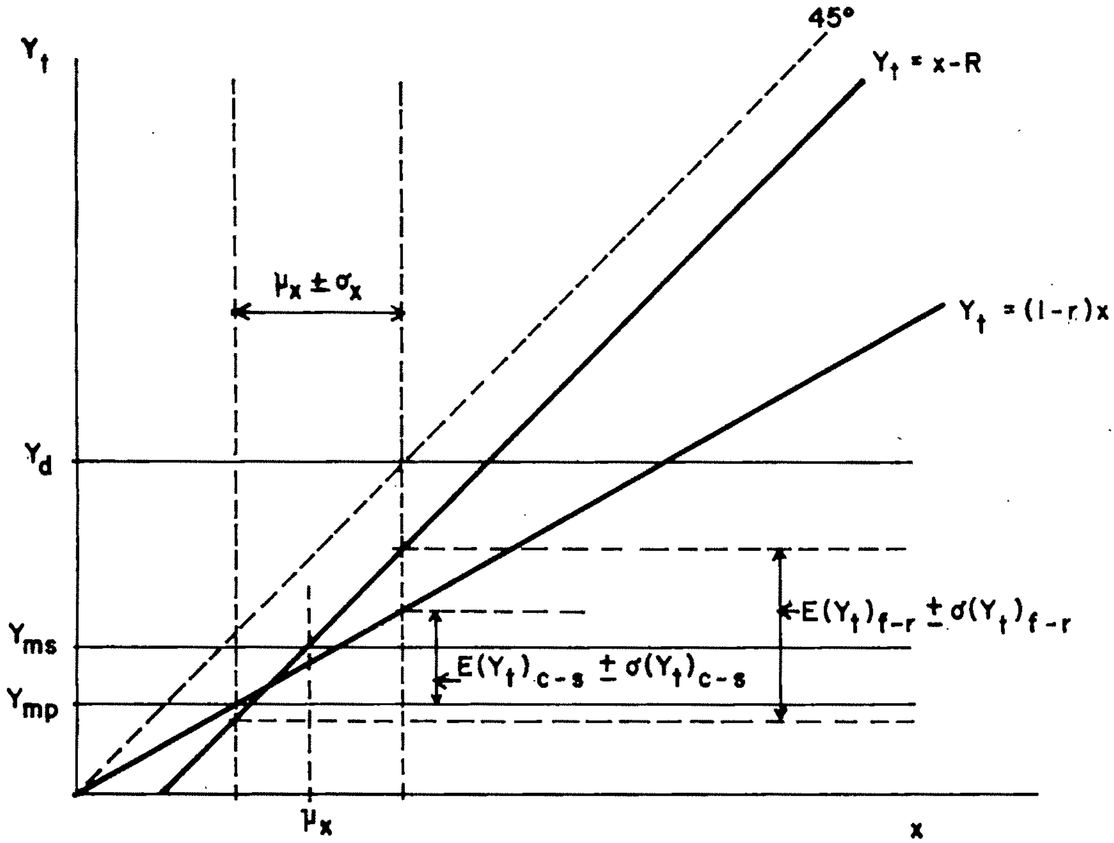

Figure 1. Choice of rental contract when peasant's expected income is low

received it. Also, this problem does not exist when tenants are not directly involved in conservation decisions. For example, landowners may specify in the lease the crops to be planted and their order of rotation. The share lease may also affect yields in the long run, if the landowner belongs to a low income group and participates in conservation decisions. In this case, a fall in yield or product prices reduces the value of the landlord's share and thereby increases his time preference rate and leads to depletion.

Up to this point, our analysis has focused only on the first and the second moments of the probability distribution. There is no reason, however, why we should not also be concerned with other aspects of the distribution. We are aware that tenure arrangements can affect the probability distribution of the tenant's income in ways other than to change its mean and variance. For instance, under the fixed rent contract with a simple escape clause, the distribution of the tenant's income is different from that obtained under other tenure arrangements, not only because its mean and variance are different, but also because its skewness tends to be different. This latter characteristic, as we shall see, may be of some importance. In our treatment of the farmer's behavior under uncertainty, we have also assumed that he ranks his opportunities by only two measures—mean and variance. This simplification is done at some cost. For example, a person's behavior is normally influenced by his desire to avoid extreme values, particularly the low extremes. He is therefore not indifferent to two distributions with equal means and variances but unequal skewness. Given these factors, our previous discussion of choice of tenure arrangement would seem to require qualification.

It is reasonable to assume that people generally attempt to avoid or to reduce the probability of very low income. In this regard, peasants are surely no exception. Of the rental contracts discussed, only the fixed rent contract with escape clause is solely concerned with reducing the tenant's probability of disaster. The peasant who pays the premium for the escape clause is insuring not so much against variability as against the disaster of starvation. One can easily think of peasants who would prefer a fixed rent contract with a simple escape clause to sharecropping, even if the share contract would give him the same expected income and a significantly lower variance.

The lack of a well-defined, one-to-one relationship between inputs and output, and consequently the importance of entrepreneurship, also creates

additional sources of uncertainty for the landowners and the peasants. Uncertainty is introduced by the existence of inputs of variable specification, e.g., the nature of the labor input is never precisely defined. The lack of a well-defined production function and the fact that input of fixed specification may result in variable performance provide scope for entrepreneurship (Leibenstein). But since people are endowed with different entrepreneurial capacities, the scope for entrepreneurship becomes another source of uncertainty. Considering these factors alone, the choice of rental contract would seem to depend partly on whether the uncertainty is perceived to be caused by the scope of entrepreneurship or by the variable specification of the inputs and partly on the tenant and landlord's assessments of their own entrepreneurial capacity.

If the main source of uncertainty is that inputs are of variable specification, then the landlord and the tenant, to protect themselves, are likely to prefer different types of rental contracts. For instance, to guard against the uncertainty of tenant labor, the specification of which is never really completely spelled out in a rental contract, the landlord would prefer a fixed rent contract. Similarly, a new tenant, to protect himself against the uncertain quality of unfamiliar land, is likely to prefer sharecropping. However, once the landlord and the tenant are better acquainted, this type of uncertainty becomes less important.

If the source of uncertainty is the scope for entrepreneurship at the farm level, then a landlord with the necessary entrepreneurial skills is likely to prefer the share contract to the fixed rent contract and take part in farm decisions so as to capture a share of the entrepreneurial income. Indeed, the landlord may even prefer sharecropping to a wage system where presumably he can capture all the entrepreneurial income. This is because the implicit reward-penalty provision of crop-sharing tends to reduce the landlord's supervision cost in that a sharecropper has greater incentive than a wage earner to follow closely the landlord's instructions. Of course, if the landlord does not have the necessary entrepreneurial ability (or does not wish to exercise it), he would attempt to protect himself from the uncertainty of entrepreneurial judgment of others by choosing a fixed rent contract. Under similar conditions, a tenant lacking the required entrepreneurial skills is likely to prefer the share contract so that he may share with the landlord both the responsibility and the uncertainty of entrepreneurial judgment and decision making. However, if the tenant is more positive in his assessment of his entrepreneurial ability than of his landlord's, he would prefer the fixed rent contract so that he may capture all the entrepreneurial income. If this argument is valid, then we would expect the share contract to be a popular arrangement between experienced farmer-landlords and young, inexperienced tenants. In the United States, at least, there seems to be some evidence of this [Gray and Turner, p. 26].

This paper has focussed on only one aspect of tenure arrangements—that they expose the landowner and the peasant to differing degrees of uncertainty. We have argued that the attitude toward risk and therefore the choice of tenure arrangement may be different depending on one's relative income position and entrepreneurial capacity. However, tenure arrangements also differ in many other important respects. They differ in that they require varying degrees of participation by the landowner in the operation of the farm, they have different transaction costs, and they impose different constraints on the tenant-peasant. Our understanding of this very important rural institution will remain imperfect until these differing aspects of tenure arrangements are brought together in an integrated and more general analysis.

Evaluation of Alternative Milk Marketing Arrangements in Southeast Florida

Anthony A. Prato

Technical and economic developments over the past two decades have altered the structure, conduct, and performance of the U.S. dairy industry. Two noteworthy developments are the successful organization of milk producers into interregional cooperatives and backward integration of food retailers into milk processing. Interregional cooperatives have increased the market power of member producers as evidenced by their ability to obtain Class I premiums for fluid milk.[1] Retailer-processor integration has improved the bargaining position of food retailers in their dealings with milk processors.

The purpose of this paper is to evaluate the potential impact of an interregional milk producers cooperative and various degrees of retailer-processor integration on the prices and returns to milk producers in southeast Florida (the area covered by Federal Milk Market Order 13).[2] Milk producers in Federal Order 13 do not belong to an interregional cooperative nor is retailer-processor integration widespread. However, the industry is concerned with the possible impacts of such arrangements on returns to milk producers and processors.

Basic Model

Various methods have been used to study the problems of food and agricultural industries. Wide use has been made of economic models that determine the optimal allocation of product supplies among alternative markets (Kloth and Blakley; Prato and Havlicek; Amin; McClelland, Polopolus, and Myers). Optimization models are somewhat restrictive for analyzing the impact of changes in economic structure and organization on industry performance and have a limited capacity to handle the time-related aspects of industrial behavior. Systems analysis can handle structural change and dynamic behavior more easily. It has been successfully used to study the consequences of alternative growth and development plans (Halter, Hayenga, and Manetsch) and a wide range of economic problems (Halter and Miller; Raulerson and Langham). Systems analysis typically involves the development of a simulation model that describes decision-making behavior. This analysis is based on the industrial dynamics (simulation) approach developed by Forrester.

The general procedure was to construct and validate a so-called basic model of the southeast Florida milk market. Impacts of an interregional cooperative and retailer-processor integration were analyzed using modifications of the basic model. The basic model consists of a system of seventy-five nonstochastic equations. Model parameters represent conditions in federal order 13 during the 1966–69 period. Three major subsystems make up the model: the physical movement of milk from production to consumption, the determination of producer, processor, and consumer prices, and the determination of returns to retailers, processors, and producers.

The milk production rate is a function of expected consumer utilization of milk and the production incentive.[3] Expected utilization measures the normal pattern of milk consumption while the production incentive measures changes in the revenue-cost position of producers. When producer revenues increase (decrease) relative to production costs, milk production increases (decreases) according to a production schedule. This and other schedules were selected according to their ability to simulate the time-related behavior of selected variables. Rates of allocation of milk to Class I and Class II uses are a function of the proportion of milk that processors allocate to these uses which in turn depends on retail utilization of Class I and Class II milk.[4] Milk allocated to Class II uses is computed as a residual, i.e., the Class II allocation proportion is one minus the Class I allocation proportion. Consumer utilization was generated by summing seasonal and time trends. Retail milk prices were not allowed to affect consumer utiliza-

Anthony A. Prato is an associate professor of economics at Colorado State University.

[1] Class I premiums cannot be completely attributed to bargaining efforts of cooperatives. Premiums can also reflect an imbalance between supply and demand, specifically excess demand.

[2] Data for Upper Florida and Tampa Bay federal orders were inadequate so they were not included in the analysis.

[3] Objections might arise from making production a function of consumption (consumer utilization in the model). While this specification would be inappropriate in an econometric model, the industrial dynamics approach does not require use of econometric-type supply and demand relationships.

[4] During the study period, Class I products included whole milk, skim milk, low fat milk, and chocolate milk. Class II products included buttermilk, flavored drinks, half and half, table cream, sour cream, ice cream, ice milk, and sherbet. Current classifications are somewhat different.

tion due to the lack of conclusive evidence that milk prices affect consumption (Prato 1973).

Minimum Class I and Class II producer prices are determined by adding a price differential (essentially transportation costs) to the Midwest basic formula price. Blend price is a weighted average of minimum producer prices with Class I and II allocation rates as weights. Consumer prices are a function of farm prices. Processor prices are derived by subtracting retail price margins from consumer prices.

Total consumer expenditures, processor net returns, and producer net returns are determined by subtracting costs and/or payments from total returns. For example, processor net returns are determined by deducting payments to producers and assembly, processing, and distribution costs from total processor returns. For a complete description of the model, see Prato (1975).

Since the basic model is nonstochastic, its equations cannot be judged by conventional measures of statistical reliability (standard errors, R^2, etc.). The model was validated by comparing the 1966–69 simulated and actual values of six variables (Fla. CLRS; Nord, USDA). Percentage differences between the observed and simulated values were smallest for blend price (1.51%), followed by producer deliveries (1.80%), Class I utilization (2.16%), proportion of milk allocated to Class I uses (2.53%) and total producer returns (2.55%).[5] The percentage difference was greatest for Class II utilization (17.56%). This inaccuracy may be due to the importation of Class II milk to southeast Florida (which is not accounted for in the model) and the inherently greater variation in Class II utilization. Based on these comparisons, the basic model was judged to be an acceptable mathematical representation of the southeast Florida milk market.

Interregional Cooperative

The cooperative model was used to analyze changes in net returns to producers, processors, and retailers that might occur if some Florida producers joined an interregional cooperative. It was constructed by altering the basic model to reflect structural and economic adjustments based on the experience of the North Central states (Jacobson and Hoddick). Adjustments are as follows. (a) Forty-two percent of the milk produced is marketed through the interregional cooperative. The remaining 58% is sold by independent producers. (*b*) Processor-oriented services provided by the cooperative enable the cooperative to negotiate a Class I premium of 30.5¢ per hundredweight on all milk.[6] (*c*) Processor-oriented services provided by the cooperative permit milk processors to reduce distribution costs on member-produced milk by 11.6¢ per hundredweight. (*d*) To finance the producer-oriented services rendered by the cooperative, coop member producers pay a 10¢ per hundredweight service fee (retained by the cooperative). (*e*) Coop member producers sell all their milk through the cooperative and independent producers sell all their milk independently of the cooperative. The distinction between member- and nonmember-produced milk was not carried over to the processor and retail segments.

Values for the cooperative model exceed those for the basic model for all six variables. The largest difference is for producer net returns which is $514.3 thousand (38%) over the entire period. Of this difference, member producers received $195.4 thousand (38%) and nonmember producers received $318.9 thousand (58%). Accumulated processor net returns for the period were $76.8 thousand (0.26%) and accumulated retailer returns were $136 thousand (2.3%) higher under the cooperative model. The monthly production rate and Class I utilization would increase by only 1% and Class II utilization by 3%.

Processor-Retailer Integration

Impacts of processor-retailer integration on returns to processors and retailers were analyzed using a modification of the basic model referred to as the integration model. Integrated processors were assumed to have lower per unit processing and distribution costs than independent processors.[7] Due to the lack of information concerning per unit costs

Table 1. Cost Differentials for Integrated and Independent Processing Plants

	Efficiency Level					
	I	II	III	I	II	III
Activity	Integrated Plant			Independent Plant		
			%[a]			
Processing	−5	−10	−15	15	10	5
Distribution	−2	− 5	− 8	8	5	2

[a] Percentage deviation above or below figures used in basic model; namely, $1.50 and $0.50 per cwt. for Class I and Class II processing costs, respectively, and $2.50 per cwt. for distribution costs.

[5] Percentage differences were computed on a quarterly basis, i.e., the average of the monthly figures for each quarter.

[6] A reviewer contends that a cooperative must control at least 70% of the milk in a given market before it can secure premiums. The 42% figure used here is a national average for milk controlled by cooperatives. The model could be rerun using higher percentages.

[7] A reviewer pointed out that Parker's study shows there are no substantial differences in processing costs for integrated versus independent plants. This point is still open to debate. If the 20% diffference used in this study is judged to be excessive, then the revenue differences reported in table 2 and corresponding conclusions would have to be revised.

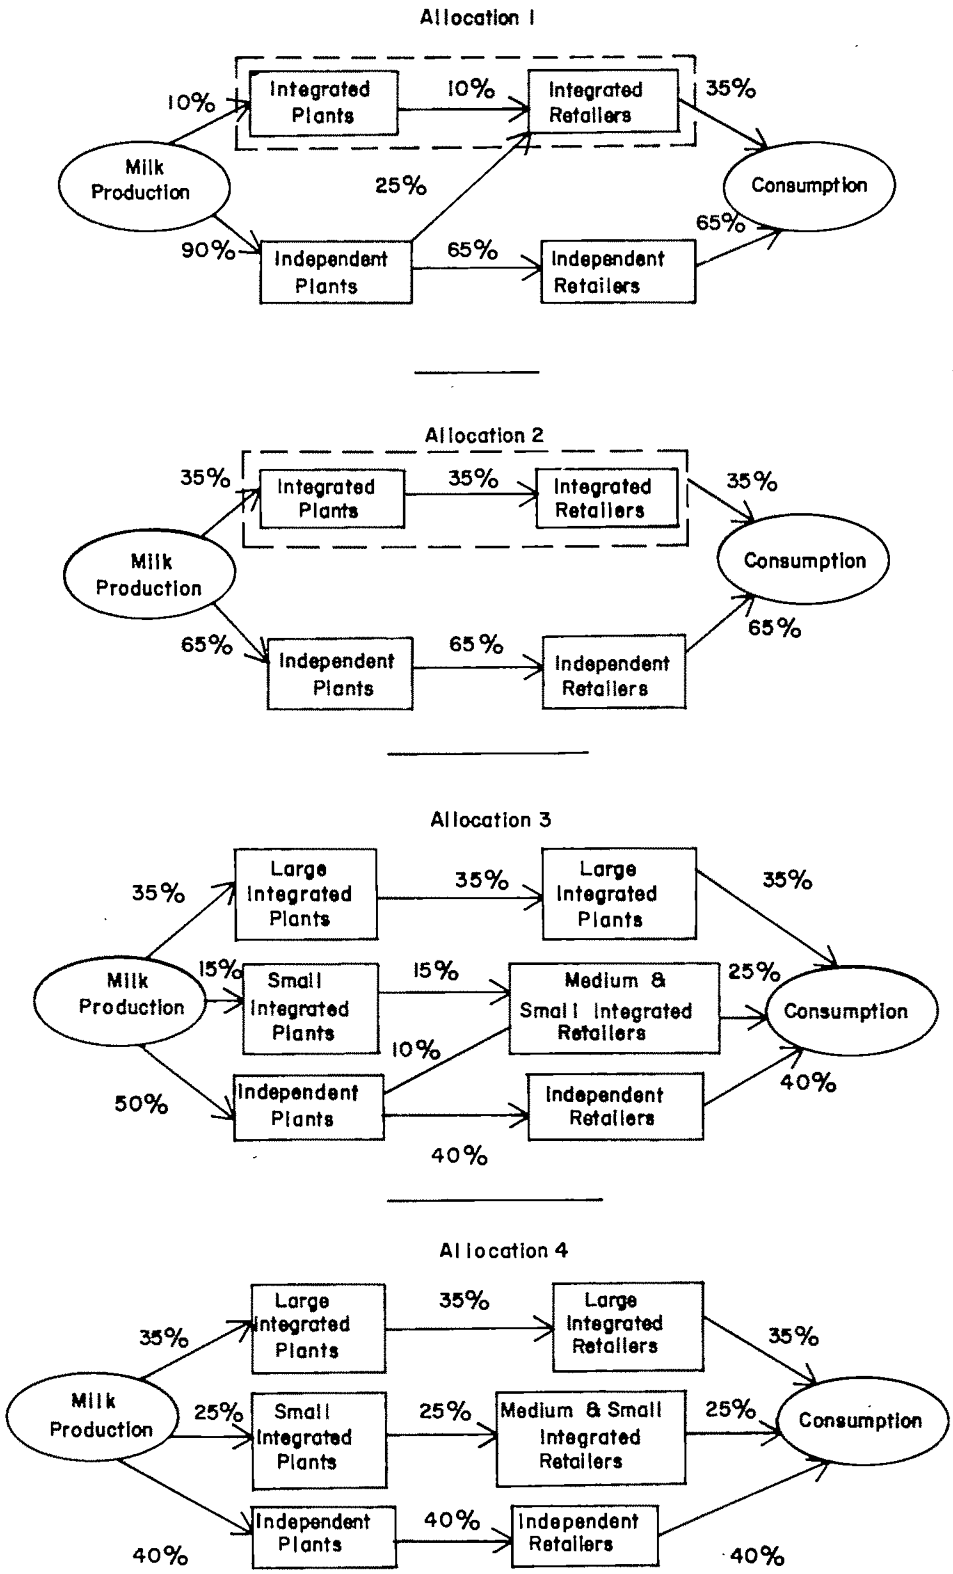

Figure 1. Alternative allocations of milk between integrated and independent plants and retailers

Table 2. Accumulated Processor Net Returns, Basic versus Cooperative Models, 1966–69

Efficiency I							
Basic[a]				Cooperative[b]			
Allocation							
1	2	3	4	1	2	3	4
$1,000							
2,490	2,786	2,915	3,001	2,591	2,859	2,989	2,561
Efficiency II							
2,813	3,108	3,219	3,294	2,886	3,183	3,296	3,371
Efficiency III							
3,136	3,431	3,525	3,587	3,211	3,509	3,603	3,667

[a] Using production and retail segments of basic model.
[b] Using production and retail segments of cooperative model.

of operating integrated versus independent plants, cost differences were defined in terms of percentage deviations from costs used in basic model. Three cost differences or efficiency levels were specified under the integration model (table 1). For each efficiency level, four allocations of producer milk between integrated and independent plants were simulated (fig. 1) Although the difference in processing efficiency between integrated and independent plants remains constant at 20% (table 1), the distribution of milk between integrated and independent plants and hence overall efficiency varies over allocation. Per unit processing and distribution costs were assumed to be the same for small, medium, and large integrated plants (fig. 1).

Each of the four allocations at three levels of efficiency was run with the producer and retail segments of the basic and cooperative models. This implies that the total quantities of milk and price levels in the integration model are the same as in the basic or cooperative model. Processor net returns under all allocations and efficiency levels are greater for the cooperative-integration than the basic-integration model (table 2). This illustrates two points. First, as the proportion of milk handled by integrated plants increases, total processor net returns increase for every level of efficiency. Second, the greater the cost reductions due to integration, the greater the increase in processor net returns. Table 2 also shows the trade-offs for increasing processor net returns by increasing the extent of integration (moving from allocation 1 to allocation 4) versus increasing the efficiency of integrated plants (moving from efficiency I to III). For example, moving from allocation 1 to 2 under basic integration and efficiency I increases processor net returns from $2,490 to $2,786 thousand, or 12%. Such comparisons give insight into the structural alternatives for improving net returns by integration.

Comparing processor net revenues in the presence and absence of integration shows that processor-retailer integration might result in no gain in total net revenue to processors if only efficiency I can be reached, minor gains under efficiency II, and significant gains under efficiency III. Moving from a cooperative structure to an integrated structure does not increase net returns unless at least 10% of the milk moves through very efficient, integrated plants or at least 65% moves through moderately efficient integrated plants.

Conclusions

Conclusions drawn from this study are conditional on the assumptions and parameter values embedded in the models. Operation of an interregional cooperative in southeast Florida would have only a negligible effect on milk production and Class I and II utilization. Net returns to producers would average 38% or $514.3 thousand greater over the 1966–69 period with the operation of an interregional cooperative. Of this amount, member producers would receive about 38% and nonmember producers 62%, if members accounted for 42% of production. Overall processor net returns would be $76.8 thousand greater (0.26%) and retailer net returns would be $136 thousand greater (2.34%) with a cooperative. Processor-retailer integration would not increase net returns over the levels in a nonintegrated structure unless at least 65% of the milk produced is moved through moderately efficient integrated plants or at least 35% through highly efficient integrated plants.

Industry Demand for Egg Clearinghouse Services

Bill R. Miller and Dennis P. Helmreich

Since 1950, significant changes in the production and marketing of shell eggs have occurred. Along with larger and more vertically integrated production units came more direct methods of marketing. Eggs were forwarded by jobbers or producers to supermarket warehouses or retail stores. Large central markets (Los Angeles, Chicago, New York, etc.) fell into disuse as they were bypassed by new shell egg market channels (Rogers and Voss). Hence, the market price quotes were based on a rapidly diminishing volume, but these quotes were used as a basis for pricing eggs which were traded directly (Rogers).

Another facet of the growth in direct marketing is the evolution in the market structure to fewer and larger egg producers. This increase in size of firms entails more uniform production methods (placements, feeding, medication, etc.) and a more uniform product. Egg producers are now producing large quantities of uniform, high quality eggs. This trend has lent credibility to the idea of trading gradeable nest run (GNR) shell eggs. This adds still another dimension to the pricing problem since, historically, prices have been quoted on a graded basis.

The Problem and Objective

During the latter half of the 1960s, a federally funded, comprehensive program of research on egg pricing was conducted. The results of this study pointed out many problems associated with market decentralization (Rogers and Voss). In an attempt to fill the price information void left by decentralization, United Egg Producers developed a short-run price projection model to provide a base point price series (Miller and Masters). Through use of this model, prices were published for two years, but its function has now been replaced by Egg Clearinghouse, Incorporated (ECI). ECI began trading eggs in November 1971. ECI trading probably does not completely reflect the current supply and demand situation. Apparently most eggs are still traded on the basis of the Urner-Barry quote or U.S. Department of Agriculture prices, but the ECI auction method of trading has the potential for more accurately establishing the price of GNR eggs at the wholesale level. USDA has established nest run specifications for determining weight classes and quality standards of GNR eggs. Trading eggs through a clearinghouse can also eliminate the need for dual grading, once at the point of origin and again at the point of destination, but will the services of the clearinghouse be acceptable to the industry? Continued acceptance and expansion of demand for this form of trading is necessary if it is to provide an efficient market price quotation for eggs. Current market price information for GNR eggs has become a vital necessity since futures contracts for GNR began trading July 1, 1974 on the Chicago Mercantile Exchange.

A study with several broad objectives was implemented in 1973 and this paper reports on one objective: project the demand for the new services of ECI.

The Data and Its Analysis

Research on acceptance of new products and services has been a focus of study for some time. One of the most common phenomena observed is an increase in sales during the introductory period when newness of the product apparently has an experimental appeal to some buyers (Eskin, Massey). These buyers try the product; then, finding it not to their liking or not fulfilling their expectations, they become inactive in the market. We hypothesized in this research that a comparison of the inactive member users of the new marketing services offered by ECI compared to the active member users would yield estimates to aid in forecasting demand among the population not yet fully exposed to, or informed about, ECI.

All members of ECI (eighty-two), effective June 1, 1973, were polled via mail questionnaire concerning their production and marketing practices and their acceptance of ECI. At the same time, a sample of eighty-five non-ECI members was chosen at random from a master list developed to represent the national poultry industry. A second questionnaire was mailed to nonrespondents after three weeks. Several nonrespondents were interviewed personally, and a random sampling of the remaining nonrespondents were interviewed by telephone. A total of fifty-three responses were obtained from the ECI members and forty-four from nonmembers.

The data were first subjected to tabular analysis to determine which variables from the questionnaires were important in terms of the amount of trade through ECI. The size of firm cross-classified

Bill R. Miller is an associate professor of agricultural economics, and Dennis P. Helmreich is a research assistant at the University of Georgia, Athens.

with all other variables from the questionnaire yielded results which suggested variables that were significantly related to the volume of business transacted through ECI.

The integrated, multifunction nature of the egg industry was apparent among ECI firms. Typically, they are involved in commission sales and purchasing for resale in addition to egg production. Only nine of fifty-three ECI members did not own a production flock. Furthermore, flock ownership was about equally distributed by size of firm, table 1, where size of firm is defined as eggs purchased, produced, or sold on a commission basis during the period of the study. Flock owners were among the largest firms; they averaged 806,000 cases handled compared to only 455,000 for nonowners.

In view of the integrated structure of the egg industry, it may be logical to ask whether they need auction markets. ECI members were asked to estimate the amount of eggs purchased (fill-in) or sold (surplus) outside of "normal" or regular marketing channels. Since fill-in and surplus are common terms among many industry members they appeared to have no difficulty completing this part of the questionnaire.

Only in the smallest firm size category, less than 162,000 cases handled, was the volume of clearinghouse trade comparable to the volume of fill-in and surplus eggs. In all other size categories, clearinghouse trade was less than 15% of fill-in and surplus and in one class, 450,000 to 840,000 cases, was less than 1%, table 1. Fill-in and surplus eggs could be traded on an auction market, but currently ECI is not capturing the existing market among its own members. Other evidence of disuse by members is the large volume of eggs sold to breaking plants relative to the size of clearinghouse trade, table 1. There is a period of the day when breaking plant stock is traded by ECI.

Apparently, the low level of trade among members is not because of recognized dissatisfaction with the service. For example, there were twenty-two members who had purchased eggs through ECI, and all indicated that they were well satisfied with the quality received. Only three indicated that egg size of the nest run product was smaller than expected. All purchasers planned to continue trading with ECI. Sellers, likewise, were generally satisfied with the service. In fact, of the four ECI members who were not satisfied and planned to discontinue their membership, none had ever purchased or sold eggs through the clearinghouse.

Of perhaps greater concern is the appeal of the clearinghouse to nonmembers. Our survey of nonmembers indicates that ECI firms are, on the average, about twice as large as nonmembers. If size or trade attributes associated with size are an important attribute of ECI trade, then long-run expansion may be difficult. We did find size to be important in attempts to discriminate between users and nonusers.

During the eighteen-month period of the study, there were eighteen members who did not trade, but they had been active in prior months. Apparently, they had tried using the service but found no continuing business use for it even though on the questionnaire they expressed general satisfaction. As it is not uncommon for purchasers of a new product or service to drop out of the market, our hypothesis was that these eighteen inactive users who were not repeating use of the service had characteristics that differentiated them from active users. Since our questions to nonmembers were parallel to questions asked of ECI members, we can compare characteristics of active ECI users with firms in the egg industry who are potential members. Discriminant analysis is one method of comparison and several discriminant models were applied to the groups of thirty-five active and eighteen inactive ECI members (Tintner). The model whose economic logic and statistical properties seemed to support the hypothesis of two different

[d] Indicates significance at 0.01 probability level.

groups contained as characteristics: size of firm, volume of breaking eggs, a satisfaction index of marketing pricing, and flock ownership. The discriminant function was determined to be[1]

$$Z = 0.01606\ X_1 - 0.0363\ X_2 - 0.01765\ X_3 + 0.00554\ X_4,$$

where X_1 = size of firm (in 1,000,000 total cases of eggs handled, January 1972–June 1973); X_2 = ownership of a flock = 0, nonownership = 1, X_3 = volume of eggs sent to breaking plants (in 100,000 cases, January 1972–June 1973); X_4 = index of satisfaction with pricing methods used for purchasing fill-in eggs and selling surplus eggs (value of 1 indicates the highest level, value of 4 is the lowest level); Z = a linear combination of the discriminant variables.

The mean Z for active traders was 0.0109 and was −0.0059 for nontrader members. Thus, a positive coefficient for firm size would project that as firms become larger they are more likely to become ECI members. Furthermore, if the large firm is a flock owner, the probability that it will be an active ECI trader increases. Also, if he is a relatively large flock owner who is dissatisfied with current pricing methods for purchasing fill-in and surplus eggs for his integrated operation, the probability increases again that he will use ECI. Finally, since large flock owners are not generally in the business of producing eggs for breaking plants, a relatively low level of trade with breaking plants is the final variable that will give him the highest probability of actively using ECI.

The discriminant function derived from the fifty-three members of ECI was applied to the observed data on forty-four nonECI members. By employing 90% confidence intervals about the group mean discriminant scores, we found that of the forty-four respondents, only three produced Z values greater than the upper confidence limit of the lower group. This would indicate that only about 7% of the sampled nonmember firms are potential users of the services of ECI. Even less potential is indicated if a higher confidence level is used.

[1] The F-value for the D-square coefficient of the function was 2.004. Variables in the function were chosen based on a cross-classification of volume of trade with all other variables provided by the questionnaire. A more complete description of this choice is presented by Helmreich.

Summary

Only about 7% of firms that do not participate in ECI were forecast as potential users of a clearinghouse for trading GNR eggs. While, on a national basis, this would represent a significant increase in ECI members and in trading, it does not represent a fast growing and universal acceptance.

This estimate should be considered short run as it depends on existing levels of satisfaction with alternate market price plans, firm size, and other characteristics of ECI members. At present, larger than average flock owners who are most dissatisfied with alternate methods of marketing appear to be the best clients for membership. As members, they are trading, in aggregate, less than 3% of their trade volume through ECI. Under these conditions, there appears to be adequate room for growth, since members are generally satisfied with ECI and a substantial fill-in and surplus market of up to 15% of total volume appears to exist among large integrated operations. General acceptance will depend on developing services that are appealing to a much broader segment of the market and will depend on member firms selling a much higher percentage of their total sales through ECI.

The Effect of Vertical Integration on the Production Efficiency of Beef Cattle Operations

Ahmed A. Araji

Cattle feeding and cow-calf operations are high investment, high risk farm enterprises. Except for those which are integrated, beef cattle enterprises are essentially marginal operations (Breimyer, p. 1). Seckler indicates that costs associated with transportation, buying and selling commission, shrinkage and death loss from the time the animal leaves the ranch until it reaches the packers are estimated between \$10–\$35 per head, depending on how far the animal is transported and how often it changes hands. Farris and Williams estimate the gain of an additional \$10 of net return per head by integrating from the cow herd to the packer. In general, all evidence points toward significant external economies associated with vertical integration in beef production. The internal effect of forward integration on production efficiency, however, has not been adequately analyzed.

Internally, production efficiency is influenced by size of operation and complementary use of resources. Thus, efficiency in beef cattle production is hypothesized as a function of size and system of operation. However, while a large number of studies show that significant economies are associated with size in all systems of beef operations, little research effort was designed to evaluate the effect of size and system on the production efficiency of beef cattle operations. Johnson and Eckert's cost analyses of four feeding systems in Nebraska showed that both system and size affected feeding efficiency, with system being the more important variable. That study, using simple regression, tested the relationship between size and input-utilization efficiency separately for each input and for each feeding system. Kearl, analyzing net income for nine feeding systems, demonstrated that the breeding system which marketed the major part or all of their young cattle as yearlings had a slight advantage over the cow-calf system.

In general, available empirical evidence relative to the effect of size and system on the production efficiency of beef cattle operations is inconclusive. The primary objective of this paper is to estimate production efficiency coefficients for three systems of beef cattle operations (cow-calf, cow-yearling, and completely integrated) and evaluate the effects of size and system on the efficiency of beef production.

Measurement of Production Efficiency

Several methods of measurement of production efficiency have been used by economists. A partial productivity index considers a single factor of production and ignores all other inputs and thus is inadequate as an overall measure of efficiency. Index numbers have been constructed to include all inputs. However, this method of measuring production efficiency suffers from the problem of choosing base years and deciding weights. Cost synthesis approaches also are used to evaluate efficiency, but this method estimates a theoretical function that is optimistic as compared to the best results observed in practice (Farrell, p. 255). A linear programming technique for measuring production efficiency which takes account of all inputs and yet avoids index number problems was developed by Farrell. Efficiency ratings estimated by this model relate the efficiency of plants of varying size and identify the optimum scale plant.

The major limitation inherent in the Farrell model is the assumption of constant returns to scale. A modification of the Farrell model that considers the effect of economies of scale was introduced by Farrell and Fieldhouse. Aigner and Chu, however, express difficulties with Farrell's approach, in that it does not conform to the law of variable proportions and in that the shape of the expansion path needs to be specified in advance (pp. 830–31). Seitz illustrates the applicability of the model proposed by Farrell and Fieldhouse to a wide variety of production functions. The shape of the expansion path need not be specified prior to estimation. He demonstrates that input-output data are expressed to allow the use of linear programming techniques for estimating a production function that conforms to the law of variable proportions, to the point of decreasing total output.

The convexity assumption inherent in the Farrell technique eliminates that portion of the function over which output decreases with increases in factor utilization. For all practical purposes, this restriction is not severe in that it excludes only those firms that might operate outside the rational range of production.

The author is indebted to J. N. Boles and K. H. Lindeborg for their helpful comments.

Procedure

A random sample was selected from the Idaho Cattlemen's Association membership records. No information was available on the operation system adopted by individual members; thus, stratification by system was not possible. One hundred and fifty questionnaires were mailed to Idaho cattle ranchers. Seventy-eight ranchers responded. In addition to information about output, labor, feed, and animal unit months (AUM); questionnaires also sought calving ratio, weaning ratio, weaning weight and death loss data. Calving ratio, weaning ratio, weaning weight, and death loss information was used to standardize the sample relative to management practices and the physical environment. Forty-eight observations were selected. The final sample included twenty cow-calf operations, seventeen cow-yearling operations and eleven completely integrated operations.

The Farrell and the Farrell-Fieldhouse techniques were used to estimate relative technical efficiency coefficients for sample observations. An inherent conceptual and empirical problem in the Farrell approach is the ambiguous measure of technical efficiency for observations falling outside the cone cod. Bressler illustrates this point and indicates his empirical studies suggest a large proportion of observations fall outside the cone cod (pp. 130–31). Examination of observations in the final study sample concerning feed, labor, and AUM inputs, indicates only 8% of the observations were outside the cone cod. The procedure used to select the final sample may have minimized the management bias relative to the proportions of feed, labor, and AUM unputs utilized by the activities in the sample.

The estimation of the frontier isoquant for the three systems is based on the assumption that observations in the three systems are on different points of the same production function.[1] Timmer examined the effect of technological changes on estimating the frontier isoquant (pp. 128–30). He demonstrates that non-neutral technological change affects the marginal rate of substitution, causing unit isoquants to cross as different frontiers are estimated for different time periods. Given the state of technical knowledge and the inputs used in estimating unit isoquant, the assumption employed in this study is justified.

The method developed by Seitz was used to estimate the efficient unit isoquant and to estimate the technical efficiency ratings of the forty-eight observations in the sample. In the case where economies of scale are important, each activity is represented by a vector $P_j = [S_j Y_{ij}]$, where S_j = scale, Y_{ij} = unit factor utilization (input divided by output), $i = 1, 2 \ldots, m$ inputs, and $j = 1, 2 \ldots,$ 48 activities. Each of the activities in turn furnishes the coefficients of the "right-hand-side" of forty-eight distinct linear programming problems. For example, the linear programming problem for any activity, P_l, selected from the set of the forty-eight activities is defined as

$$\text{(1)} \qquad \max X_o = \sum_{j=1}^{n} X_j,$$

subject to $X_j \geq 0$,

$$\text{(2)} \qquad \sum_{j=1}^{n} X_j\,(P_j - S_l E_1) \leq (P_l - S_l E_1),$$

where X_j = the level of operation of the jth activity; ΣX_j = maximum output that can be achieved from the set of inputs for the jth activity subject to the requirement that the weighted average scale of the activities in the optimum basis is precisely equal to the scale of the jth activity; P_j = a vector equal to $[S_j Y_{ij}]'$; S_j = scale and is a single element or scalar incorporated in the vector of the jth activity; Y_{ij} = input-output ratio; $i = 1, 2, \ldots, n$ inputs; $j = 1, 2, \ldots, n$ activities; P_l = is a selected activity out of the set of forty-eight activities and represented by the vector $[S_l Y_{lj}]'$; and $E_1 = [1.0, 0.0, \ldots, 0.0]'$.

The set of convex combination of the optimum basis defines one hyperplane of the efficient unit isoquant. The technical efficiency given scale (TES) rating of the activity P_l is equal to $1/X_0''$, where X_0'' is the optimum value of the objective function. Upon the solution of the forty-eight linear programming problems, the efficient unit isoquant is completely defined in terms of those activities for which TES = 1.00.

The linear programming problem for the selected activity, P_l, where constant return to scale is assumed is defined as

$$\text{(3)} \qquad \max X_0 = \sum_{j=1}^{n} X_j,$$

subject to $X_j \geq 0$,

$$\text{(4)} \qquad \sum_{j=1}^{n} P_j X_j \leq P_l,$$

where P_j is a vector equal to $[Y_{ij}]'$, and Y_{ij} and X_j are defined as above. The level of technical scale efficiency (TSE) is given by the ratio $1/X_0''$ where X_0'' is the optimum value of the objective function. The complete description of the computational procedures and the Fortran System of the above models is shown by Boles.

The economic and price efficiency ratings for the forty-eight activities were determined using the method described by Seitz. The variables are defined as follows: (*a*) Two measurements of output were considered. Output is expressed in pounds of

[1] The difference between the "frontier" concept presented by Farrell and the "average" concept is that the "frontier" concept defines a production function that expresses maximum product obtainable from the combination of factors at the existing state of technical knowledge (Carlson, pp. 14–15), while the "average" concept defines a production function that is fitted through a series of observations on the firms for output and several inputs. For further discussion of the relative merits of a frontier function and one estimated with averaging techniques, see Aigner and Chu (pp. 826–27).

liveweight production excluding death loss, 20% heifer replacement, and 1% bull replacement but including home-consumption and cull animals. Output is expressed in the value of the product produced.[2] (*b*) Three inputs were used in estimating production efficiency. Johnson and Eckert show that feed constitutes 68%–77% of total cost of beef production depending on the system of operation. All feed items were converted to digestible energy and measured in alfalfa equivalents. Johnson and Eckert show that labor accounts for 4%–7% of total cost of beef production, depending on the system of operation. Labor was measured in manhours and included both family and hired labor. Western ranchers depend on public land grazing for an average of five months a year. Grazing was measured in animal unit months (AUM) and includes grazing on federal, state, and private land. (*c*) Output is used as a measure of scale.[3]

Analysis of Results

Optimal Size

The size distribution of observations in the final sample ranged from 10,600 pounds to 479,700 pounds annual output. The measures of technical, price, and economic scale efficiency relate the efficiency of beef operations of varying size and identify the optimum scale of operation. Relative to other activities in the sample, an operation with annual output of 479,700 pounds has 100% technical, price, and economic scale efficiency ratings. This size of operation is optimal when total product or products' value is used as a measurement of output. The measures of technical, price, and economic efficiency given scale indicate the degree to which inefficiency observed in an operation of a given size is due to level of factor usage, the proportion utilized, or some combination thereof. By accounting for the scale effect, several activities emerged with 100% technical, price, and economic efficiency given scale.[4]

System's Effect

The effect of system on the efficiency coefficients given scale is tested in the following model.[5]

$$(5) \qquad H = \frac{12}{N(N+1)} \sum_{i=1}^{K} \frac{R_i^2}{N_i} - 3(N+1),$$

where H = chi-square with $K - 1$ degrees of freedom, $N = n_1 + n_2 \ldots + n_k$ observations, R_i = the sum of rank in the ith system, $i = 1, 2, \ldots, K$ system.

The computed H-values for the efficiency coefficients given scale, are less than $\chi^2_{2\ \text{d.f.},\ \alpha = 0.05} = 5.99$, indicating no statistically significant difference between the three systems of beef operation with respect to technical, price, and economic efficiency given scale (Araji 1975). Therefore, after the scale effect is accounted for, system of operation does not seem to significantly influence the internal efficiency of beef cattle operation with respect to feed, labor, and AUM inputs.

Implications

The results of this study indicate that after the scale effect is accounted for, the system of operation does not significantly influence the internal efficiency of beef cattle operations with respect to feed, labor, and AUM utilization. Optimum size is estimated at 479,700 pounds of annual liveweight production. Managerial decision to achieve the optimal size of operation through specialization or vertical integration is a function of the fixed cost and external economies associated with each rather than internal efficiency (Araji 1975).

The completely integrated system operating at optimal size has a potential fixed cost saving of $30,164 annually compared to optimal size cow-calf system and $15,971 compared to the cow-yearling system (table 1). Costs associated with transportation and auction market fees from the time the weaner leaves the ranch until it reaches the feedlot are estimated at $12.22 per head (table 2). This cost does not include shrinkage, death loss, and medication associated with the transferring of beef animals. This completely integrated system has an advantage in transportation and handling costs of $4,546 annually, compared to the optimal size cow-calf system, and $1,728 compared to the optimal size cow-yearling system. In general, fixed cost

[2] Since the value of a pound of calf is not equivalent to the value of a pound of yearling, which is not equivalent to the value of a pound of finished beef, standardizing output in terms of the value of the products produced will provide a more uniform unit of measurement. Expressing output in terms of total revenue for the purpose of measuring production efficiency could not be justified theoretically unless the products under consideration have similar demand structures. Prices of calf, yearling, and finished beef are highly correlated and the three beef products have similar demand structures (see Araji 1971).

[3] The prevailing Farrell-Fieldhouse-Seitz model uses output to represent scale. This treatment could underestimate the scale effect and overestimate technical efficiency. However, for the purpose of this study, output is considered the best feasible variable to represent scale.

[4] For complete information on relative efficiency ratings of the forty-eight activities in the sample study, see Araji (1975). Since efficiency coefficient is measured as the difference between the firm's actual output and the efficient isoquant, the efficiency coefficient is a catch-up of many other factors. Two important ones should be noted: (*a*) random disturbances (in the case of this study, the errors are small compared with the variation in efficiencies and for all practical purposes, this bias is negligible [Farrell, p. 263]); and (*b*) management bias (optimum size of beef operation requires managerial input with relatively high education, high economic motivation, high scientific orientation, and low risk aversion (Araji and Finley)). While it is not an easy task to incorporate the human factor in the estimation of production efficiency, the procedure used in the selection of the final sample should have minimized the management bias in estimating efficiency coefficients for the observations in this study.

[5] The distribution of the efficiency coefficients estimated by the Farrell-Fieldhouse technique does not satisfy the normality requirement for the use of parametric statistics to test the effect of system on the efficiency of beef production. The Kruskal-Wallis test is a nonparametric counter-part of one-way analysis of variance and is a useful test when the normality requirement cannot be satisfied (Colquhoun, pp. 191–95).

Table 1. Total Capital Investment and Annual Fixed Cost Associated with the Optimum Size of Beef Cattle Operation by System

System	Optimal Size (lb.)	Number of Animals[a] Unculled	Culled	Cow Unit[b]		Total Capital[c] Investment ($)	Total Annual[d] Fixed Cost ($)	Annual Fixed Cost (¢/lb.)
Cow-Calf	479,700	719	192	995		1,019,875	69,222	14.4
Cow-Yearling	479,700	566	134	791		810,775	55,029	11.4
Completely Integrated	479,700	372	89	524	ranch	537,100	36,454	7.6
					feedlot	19,200	2,604	0.5
						556,300	39,058	8.1

[a] Unculled animal refers to weaner at 400 lb. average weight, yearling at 600 lb. average weight, and finished beef at 1,050 lb. average weight. Culled animals refer to cows and bulls at 1,000 lb. average weight.
[b] Cow-unit includes 20% heifer replacement and 1% bull replacement plus 5% death loss from birth to weaning, 2.3% death loss from weaning to yearling, and 2% death loss in the feedlot. Calving ratio of 98% was used.
[c] Capital investment of $1,025 per cow-unit was used (see Araji 1975, appendix b—table 1). Capital investment of $96 per head for feedlot capacity of 200 head was used (see Araji 1975, appendix B—table 3).
[d] Annual fixed cost of $69.57 per cow-unit was used (see Araji 1975, appendix B—table 2). Annual fixed cost of $7 per head for feedlot is used (see Araji 1975, appendix B—table 4).

Table 2. Transportation and Handling Cost by Class of Beef Animal

Item	Type of Beef Animals: Weaner $/Head	Yearling $/Head	Total $/Head
Transportation[a]	$2.80	$3.64	$ 5.72
Auction[b]	2.40	2.80	5.20
Yardage and feed[b]	0.50	0.80	1.30
Total	$4.98	$7.24	$12.22

and transportation and handling costs associated with the three systems of beef operation strongly justify vertical integration in beef cattle production. The completely integrated system operating at optimum size has a potential annual net benefit of $34,710 compared to the optimal size cow-calf system and $17,699 compared to similar size cow-yearling systems.

Incorporating Small Group Activities into Agricultural Economics Classes

Fred C. White and Sherry K. White

Traditional classroom instruction which consists almost entirely of lecturing is often criticized because it relies heavily on passive learning methods and ignores other effective methods which actively involve students. Consequently, there is a need in college classrooms to generate more student participation that will make the subject matter not only more interesting but challenging. Small group activities can help solve the problems that many college instructors encounter. Although small group activities are certainly not new, their limited use in the social sciences indicates that instructors may not be fully aware of the potential applications and effectiveness of these methods. The objectives of this paper are to describe areas in which small group activities may be incorporated into agricultural economics classes and to evaluate their usefulness in supplementing other teaching methods.

Teaching improvement workshops in agricultural economics have emphasized such techniques as television lectures; audiotutorial instruction, including slide sets, films, tape cassettes, etc.; independent study; and computer-assisted instruction (Workshop on the Improvement of Education in Agricultural Economics). Use of small group activities was mentioned in these workshops only in conjunction with computer-assisted instruction. Although the latter methods were considered effective in motivating students, emphasis in describing the techniques was concerned with computer application rather than small group activities. Furthermore, other methods for incorporating small group activities into agricultural economics classes were not explored.

Procedure

Small group activities were incorporated into agricultural economics classes at the University of Georgia during the 1974–75 academic year. These activities were used in classes on aggregate economic analysis and agricultural policy; they are junior level, required courses for agricultural economics majors but are also taken by other majors. Class size ranged from twenty to thirty students. Each small group contained from three to six students but size could be varied as appropriate.

To evaluate the effectiveness of small group activities, test scores for students in these classes were compared to scores of previous students. In addition, students were asked to complete a questionnaire evaluating these activities. Basic information on cumulative grade point average and major was obtained for each student in order to determine which type of student would show favorable response to this teaching method.

Small group activities can be used in various forms to teach application of economic principles. More specifically, the class may be divided into groups to solve problems, gather and analyze information, or discuss ideas. Each of these activities is described below.

Problem-Solving Groups

The instructor first presented basic economic principles that students were expected to use. Since solving problems requires a capacity to discern the problem and identify alternative solutions, problem solving provided an opportunity to apply economic principles. For selected problems, students were divided into small groups in anticipation that discussion with other students would help develop a strategy for problem solving. When less able students were temporarily lost, this approach provided the instructor an opportunity to work with these students while other groups worked independently of the instructor. The instructor closely monitored student progress and acquired immediate feedback from them. In an aggregate economic analysis class, students analyzed problems dealing with unemployment, recession, and inflation. The small groups identified potential problem situations and then attempted to formulate policies to solve these problems.

Resource Groups

In some instances, larger problems can best be analyzed by considering individual components. The class first participated in dissecting such problems into workable components. Then, small groups which had access to resource materials (through the instructor, library, etc.) worked on separate but related parts of a larger problem. After each small group researched its particular part, the information was fed

Fred C. White is an assistant professor of agricultural economics at the University of Georgia, and Sherry K. White is an instructor at the Athens Area Vocational-Technical School, Athens, Georgia.

back into the total group in a synthesis session to reassemble the components.

In an agricultural policy class, students analyzed a questionnaire obtained from a mail survey of Georgia farmers. The completed questionnaires supplied information on farmers' problems and their perceptions of these problems. The class was divided into groups to cross-classify farm problems by age of operators, size of operation, and region of the state. Each group was responsible for analyzing one of these areas and for summarizing the results. A fourth group was responsible for developing a completed manuscript from the contributions of other groups. Although the study was designed to give students a better understanding of farm problems, it resulted in a research publication that also provided useful information for agricultural and governmental leaders.

In another application of this approach, students were assigned the problem of analyzing a national land use policy. Each group assumed identity of some special interest group, e.g., agriculture, forestry, mining, environmental agencies, local government, or state government. Using library materials, including Congressional hearings, students were to determine what their special interest group wanted from a national land use policy. Based on outside resources, the groups expressed different perspectives for land use policy to the class. Then the class developed a general outline for a land use policy that would integrate diverse social viewpoints. This method showed students how policy evolves and the need to mesh and compromise before an answer is developed.

Discussion Groups

Discussion classes primarily involved an interchange of ideas and knowledge among groups of students, with active participation by the instructor. In this type of group, students researched an assignment and discussed the topic informally with the entire class. However, prior research was not necessary for effectiveness; an informal debate could result by dividing the class into debating teams. Discussions were used to focus on attitudes of students and to allow them to critically evaluate their own attitudes by evaluating others' opinions. In addition, this activity appeared useful as a review at the end of a unit.

All topics are not equally well suited for small group discussion. Topics which require the student to acquire fairly straightforward information may be best suited for lecturing, reading, or other modern teaching techniques (Beard). However, other issues which are more difficult to resolve may be profitably explored through discussion groups.

Evaluation

Small group activities were evaluated with respect to course coverage, motivation, development of communication skills, interpersonal relationships, and instructor's responsibility. Also, attention was focused on student performance and student response to this method.

Small group activities did not greatly alter coverage of material during the experiment, because these activities were used to supplement other teaching techniques. However, these methods appear appropriate for an in-depth coverage of material rather than breadth of coverage. Since each student, as a group member, actively investigated some topics in detail, he became much more familiar with these topics.

Use of small groups provides the student with a variety of learning methods, an opportunity to actively participate in the learning process, and a chance to work with other class members. In most cases, these activities created an environment of healthy competition among the small groups, which stimulated student involvement.

In a recent survey of businesses and government agencies which employ agricultural graduates, employers repeatedly suggested that college graduates needed improved communication skills (University of Georgia). Students often have limited opportunities to develop these skills. However, in discussion groups, students must formulate and organize their ideas on a specific subject, express their ideas verbally, and evaluate other students' opinions. Such a dialogue fosters the development of critical thinking and oral communication skills. Furthermore, problem-solving and resource groups can be used to improve writing skills.

Dubin and Taveggia report that learning is considered an outcome of interpersonal activity. Small group activities strengthen both student-teacher and student-student relationships. With these activities, students recognize that the instructor's primary role is to facilitate learning, not simply to dispense information. Thus, the instructor has a better rapport with the students. Moreover, small group activities differ from general discussion classes which involve only student-teacher interchange. In the student-teacher interchange some students may dominate the class discussion, while others are reluctant to participate. Students have a greater opportunity to participate when the class is divided into smaller groups, and many will share their ideas with two or three class members but not with the entire class. Furthermore, students are eager to help one another and working together helps create a class identity.

In general, using small group activities does not alter the instructor's responsibility for establishing course objectives and a timetable for covering the material. Their use allows the instructor to employ multiple teaching techniques which Kendrick cites as a requirement for effective teaching. Thus, small group activities aid the instructor in creating an environment in which learning can take place. By working with small groups, the instructor can ensure that everyone is participating in problem solv-

Table 1. Effect of Small Group Activities on Student Performance

	Regression Results[a]	
Dependent variable: Test score		
Constant	−10.93	−10.98

ing and can aid those students who otherwise display little interest in the material or who would have difficulty with the assignment. Other students who understand the material could be moving at a faster pace, while working independently of the instructor.

When students are actively involved in small groups, the instructor devotes less time to formally structured presentations. However, this method requires that the instructor be well prepared and have a thorough knowledge of the subject matter. In addition, the instructor must be able to handle many situations to provide guidance and encouragement to students.

Student Performance

Although students applied economic principles in small group activities, each student was held individually accountable for achieving course objectives. Thus, test scores could be used to measure the impact of these activities on student performance. Test scores for those students who had participated in small group activities were compared with scores of students in other classes taught by the same instructor but without the benefit of small group activities. Data from a sample of sixty-two students, equally divided between classes with small group activities and without, were used in a regression analysis to measure differences in student performance resulting from these activities. The two classes completed similar exams over material for which only one class had used small group activities. These individual test scores were used as the dependent variable in the regression analysis. Since it was necessary to correct for differences in student ability, each student's average score on previous tests was used as an independent variable. A dummy variable whose value was one for students in the class with small group activities and zero, otherwise, was the other independent variable.

The regression results are shown in table 1. The principal result of this analysis indicates that, on the average, students who participated in small group activities scored 4.38 percentage points higher than others. Further analysis using two dummy variables to divide the sixty-two observations into three groups indicated that the advantage of small group activities applied equally to students regardless of ability.[1] Participation in small group activities raised the expected test score 4.41 percentage points for students with above average scores on previous tests and 4.37 percentage points for students with below average scores.

These regression results are not definitive evidence on the merits of small group activities, but, in general, it was felt that students were better trained after applying principles they had learned. Other applications of small groups may not be evaluated in such a straightforward manner. For example, these methods provide opportunities for students to study certain topics in greater detail. Thus, with the implementation of small group activities, course coverage may vary somewhat from previous offerings.

Student Response

In addition to informal critiques, students were asked to complete a questionnaire on the effectiveness of small group activities. The questionnaire also included questions on the student's academic major and cumulative grade point average in order to identify which type of student favored these activities. In general, student reaction to small group activities was favorable. Responses from the

[1] This regression equation included two dummy variables. The first dummy variable had a value of one for students in the class with small group activities who had an above average mean test score on previous tests and a value of zero otherwise. The second dummy variable had a value of one for students in the class with small group activities who had a below average mean test score on previous tests and a value of zero otherwise.

Table 2. Student Reaction to Small Group Activities

Student Characteristics	Student Reaction: Strongly Favor	Favor	Indifferent, Object, Strongly Object	Number of Students
	.... %			
Cúmulative grade point average:				
Less than 2.4	50	50	0	8
2.4 to 2.8	50	50	0	14
2.8 to 3.2	63	37	0	8
Greater than 3.2	75	25	0	8
Major:				
Agricultural economics	57	43	0	23
Other	53	47	0	15

thirty-eight students from two classes who completed the anonymous questionnaire on these activities are presented in table 2. The responses of students with less than a 2.8 grade point average were equally divided between strongly favorable and favorable, while students with higher grade point averages tended to be strongly in favor of these activities. Over half of the responses were strongly favorable for both agricultural economics majors and other majors (table 2).

In addition, students suggested specific ways that the method was beneficial. Some students indicated that they learned more because they were involved in the research and were able to defend a viewpoint. Furthermore, some recognized that they had learned because of exposure to various viewpoints. Some said it created a more relaxed atmosphere and helped them to interact better with other students. Competition was another key comment made by students; the healthy competition between small groups stimulated active participation. Efficient use of class time was also mentioned by several students.

Limitations

Small group activities involve instructor's time and effort. To the extent that these activities are well planned and executed, they may involve more time in planning than would the lecture technique. However, the time requirement is highly variable depending on the activity. The instructor's leadership role in the classroom is expanded to include developing and directing group activities. To make sure that these activities proceed in the right direction, the instructor must remain alert to each group's progress and problems.

These activities are time consuming. Students are involved in a thorough examination of economic principles being applied to a rather limited problem. Thus, this method may be inefficient when a wide range of material must be covered in a specified period of time.

Class size may be a problem. The class may be too large for the instructor to successfully coordinate all groups. If the class is very small, it may not be necessary to use small groups, because there is more freedom to develop interpersonal relationships.

Conclusions

Small group activities are particularly useful in giving students an opportunity to apply economic principles. Using these activities as supplements to more widely used teaching techniques would provide welcomed variety to students, as well as a vehicle for instructors to maintain contact with individual students. These methods can be used in agricultural economics classes to improve both problem-solving skills and communication skills. Students learn by doing, and these activities provide opportunities for greater student involvement and participation. Student performance resulting from these activities and students' comments helped to substantiate our belief that small group activities have a place in the college classroom.

Participation by AAEA Membership in the 1974 Election

Barbara J. Redman and John C. Redman

The membership of the American Agricultural Economics Association is widely distributed throughout the world. In the United States, most members are affiliated with the land grant college system or the U.S. Department of Agriculture. The purpose here is to analyze member participation in the 1974 election for president and directors of the AAEA and to determine if affiliation with a land grant institution influences participation and if this participation varies significantly by region.

In accordance with the Bylaws, data are kept on the sending and return of ballots by qualified (paid) members. Also, data on total membership (unpaid and paid) are available in zip code order. This facilitated further sorting into cities in which land grant universities are located and for the rest of the state. Also, Canadian and foreign categories were established.

Slightly more than two-fifths of the individuals who were members in February 1974 voted; about 71% paid dues by April 1 and 58% of those paid returned a ballot (table 1). Less than one-half of the U.S. members in February made the necessary effort and had their vote registered.[1]

To determine if any regional differences in the United States exist, seven regions were arbitrarily delineated, except Kentucky was included in the South (see Redman, p. 145, map), and data were arranged accordingly (table 2). The variance test for homogeneity of the binomial distribution (Snedecor and Cochran, p. 240) showed no significant differences among regions overall, whether using either the percentages paid or the percentages voting.

A test was also made to determine if land grant status had a significant effect on voting. The Washington, D.C. area was omitted from the analysis. The close proximity of Washington to the University of Maryland and the non–land grant areas of Maryland and Virginia made the problem in classifying land grant cities and the rest of the state too great. However, the omission probably did not affect results greatly, since the overall voting in the Washington area did not define either extreme.

The proportions of voting members were calculated for each land grant university city and the rest of the state and grouped into regions, excluding the Washington, D.C. area states (table 3). A two-way analysis of proportions (Snedecor and Cochran, pp. 243–47) was used, which has the added advantage of separating the effects of regional and land grant university influence and testing for both simultaneously.

The proportions p_{ij} were regarded as normally distributed variables with variance

$$\frac{p_{ij}\,q_{ij}}{n_{ij}},$$

with p referring to the proportion of voting members to eligible (paid) members, q to the proportion of eligible members who did not vote, i to the region, j to the land grant status and n to the eligible (paid) members. The proportions and differences in the analysis were weighted inversely as the variances.

One of the (null) hypotheses involved in the two-way analysis was that the proportions of voting members would be the same regardless of land grant university status. Land grant university influence might be expected to be significant as those members tend to be more active generally in

Barbara J. Redman is a graduate student in economics at Iowa State University, and John C. Redman is a professor of agricultural economics at University of Kentucky.

The investigation reported here is in connection with a project of the Kentucky Agricultural Experiment Station and is published (as Paper No. 74-1-171) with approval of the director.

[1] Ballots were mailed to a total of 2,827 qualified members, which exceeded those qualified in 1973 by 757, and 58.37% returned their ballots as compared to 55.75% in 1973. No doubt much of this increase can be attributed to the fact that in February each unpaid member was sent a "Final Notice to Maintain Eligibility for Voting."

Table 1. Total AAEA Membership and Voting Response, 1974

Category	United States	Canada	Other	Total
Total membership (February)	3154	302	531	3987

Pacific	72.535	55.556
Mean	69.607	54.873

the usual professional activities, especially publishing in the *Journal*. This perhaps is explained by the concentration of professionals, which facilitates research, exchange of ideas, peer pressure, etc. One could logically expect this professional activity and interest to extend to voting in election of officers of the professional society. The extremely strong land grant influence which emerged may dwarf the regional influences so as to hide the latter effect in the homogeneity test using total data.

As no significant differences among regions were found in total data using the variance test for homogeneity of the binomial distribution, there had appeared to be no a priori reason to expect any when using the analysis of proportions on the further regional breakdown according to land grant city and the rest of the state. However, there was a significant difference among regions (table 4) under this second test which isolated regional and land grant university effects.

It may also be argued that the centers of the greatest agricultural economic activity would have

Table 4. Z Values for Main Effects in Two-Way Analysis of Proportions

Land grant institutions vs. rest of state	$Z = 6.4512^a$
Regions, combined effects	$= 5.1484^a$
Regions, land grant cities only	$= 4.2533^a$
Regions, rest of state only	$= 2.9009^a$

[a] Significant at $\alpha = 0.05$.

Table 5. Z Values for Individual Regions

Region (versus all other regions)	Land Grant Cities Only	Rest of State Only
New England	2.5799[a]	2.3090[a]
Mountain	2.9290[b]	1.2629
Plains	3.5890[b]	1.7792[c]
Pacific	1.9230[c]	1.3531
South	1.8774[c]	1.3593
Midwest	2.0766[a]	1.9190[d]

[a] Significantly higher at $\alpha = 0.05$.
[b] Significantly lower at $\alpha = 0.05$.
[c] Significantly higher at $\alpha = 0.10$.
[d] Significantly lower at $\alpha = 0.10$.

the greatest participation in the professional society. Further analysis of proportions voting to determine which regions account for the main effect observed in table 4 do not support this fully (table 5). Differences and variances were calculated for each region versus each remaining region within each land grant college status classification and weighted and combined to form the Z value for each region. In the land grant analysis, the New England, Pacific, South, and Midwest regions resulted in significantly higher Z values, and Mountain and Plains regions were significantly lower. For the non–land grant areas, New England was significantly higher at the 5% level. The Midwest non–land grant participation was significantly lower at the 10% level.

Some plausible explanations could be suggested as to why the regional significances occurred. The New England area has several land grant universities, each serving a smaller area and thereby offering better communications and cohesiveness among all members in the area. The reverse may be proposed for the Mountain area's low participation. This, however, does not explain the participation in the Plains and Midwest. One relevant point could be the small difference in proportions between the land grant and non–land grant activity in the Plains. In addition, the location of election candidates may influence their respective regions' participation.

Profiles of Heads of Departments of Agricultural Economics in the United States

Dilip Pendse

In recent years, the *Journal* has enlightened its readers on such subjects as the spatial distribution of membership in the American Agricultural Economics Association, the institutional affiliation of authors contributing to the *Journal*, and its use as a reference in research (Finley and Barger, Holland and Redman, Redman). Information about persons who direct departments of agricultural economics in the major universities is one subject that has received little attention in the *Journal*. Although department heads hold positions of substantial responsibility, little information is available about their professional and academic achievements, their institutional affiliations, their areas of specialization, and the like. The purpose of this note is to provide a group profile of the persons who headed the fifty departments of agricultural economics in the fifty major U.S. universities as of August 1, 1975.[1]

The information reported is based mainly on the *Handbook-Directory* of the members of the AAEA published in 1966 and 1972. Some additional data concerning academic and professional achievements, publications, and awards were gathered from issues of the *Journal* published from 1950 to 1974. Reliance on secondary data has naturally put severe limitations on the kind and amount of information provided in this note. Nonetheless, the information presented here should be of interest to AAEA members.

No department head is a woman, and except for one born in Germany, all were born in the United States, in twenty-eight states. The largest number, fifteen, come from the states in the western North Central region; the states in the North Central and the South Central regions number eight each; the states in the North Atlantic, the South Atlantic, and the Far West number six each.

Data on the institutions awarding Ph.D.'s to department heads and their approximate age are presented in table 1. The table shows that all department heads have earned the Ph.D., awarded by seventeen institutions, mostly land grant universities.[2] The University of Minnesota (8), the University of California (6), Iowa State University (4), and the University of Wisconsin (4) have awarded the Ph.D. to 44% of the department heads. This is likely related to a number of factors including, but not limited to, the size of the department, the diversity of graduate programs, the number of Ph.D.'s awarded each year, and the "prestige" attached to graduates of particular institutions.

Sixty percent of the department heads were born prior to 1930. The youngest department head is thirty-five years of age, while the oldest is sixty. The majority of them are forty-five years of age or over. Data presented in table 1 suggest the number of vacancies that may occur in department head positions in the next few years. Data presented in table 2 indicate that all department heads received the Ph.D. between 1949 and 1969, 56% during the 1949–59 period and 44% during the 1960–69 period.

A simple approach was taken to assess professional and academic achievements of department heads. First, all the articles, notes, discussions, and reviews authored or coauthored by department heads in the *Journal* during the twenty-five year period from 1950 to 1974 were surveyed. Second, data were gathered on department heads who had been either elected president of the AAEA, worked as the editor of the *Journal*, won AAEA awards for excellence in teaching, extension work, and published research, or were recognized for directing award-winning M.S. or Ph.D. theses. Third, data were obtained on department heads whose scholarly achievements have been recognized in the Who's Who directories.

Department heads have authored or coauthored a total of 184 articles (including reviews, notes, and discussions) in the *Journal* during the 1950–74 period (table 2). As table 2 indicates, thirteen or 26% of the department heads have not authored a single article in the *Journal* in the past twenty-five years. The largest proportion of nonauthors belong to the group of department heads who received their Ph.D.'s in 1965 or later years; the smallest

Dilip Pendse is a research associate at Virginia Polytechnic Institute and State University.

The author is grateful to J. Paxton Marshall, Joseph Havlicek, Jr., Sandra S. Batie, M. C. Conner, and Donald McKeon for their helpful comments on earlier drafts of this paper, as well as to two anonymous reviewers for their helpful comments; the incorporation of their suggestions has greatly enhanced the quality of the paper.

[1] Although the list of department heads in my possession contains names of fifty-four persons (thirty-two "heads" and twenty-two "chairmen"), data on four department heads were not available in any of the *Handbook-Directories* of the AAEA members or in the Who's Who directories.

[2] Presumably these Ph.D.'s are in the fields of economics or agricultural economics. It is impossible to identify these degrees since the *Handbook-Directory* of AAEA members does not indicate in what field the Ph.D. was obtained.

Table 1. Age Composition and Institutions Awarding Ph.D.'s to Heads of Departments of Agricultural Economics

Institutions Awarding the Ph.D.	Year of Birth 1915–19	1920–24	1925–29	1930–34	1935–40	Total

proportion belong to those who earned Ph.D.'s during 1949–54. Seventy-one percent of the *Journal* articles authored by the department heads are by those who obtained their Ph.D.'s during the 1950s. Furthermore, 46% of the department heads with some *Journal* publications have contributed less than five articles per person in the past twenty-five years. Four department heads have authored fifty-four articles in the *Journal* (29% of the total) during the same time period.[3] Of those who have authored articles in the *Journal,* the 1949–54 group has had on the average 6.5 *Journal* articles in the past twenty-five years, as compared with 5.3 per person from the 1955–59 group, 4.1 per person from the 1960–64 group, and 2.4 per person from the 1965–69 group.

Only one head has been president of the AAEA; only one has been editor of the *Journal* (for two years). One department head has been a three-time cowinner of the AAEA published research award, one has won the AAEA distinguished teacher award, and three have been recognized for directing the AAEA award-winning M.S. theses.

Twenty-four or 48% of the department heads are recognized in at least one of the Who's Who directories. Nineteen are listed in the *American Men of Science,* eleven in *Who's Who in America,* two in the *Directory of American Scholars,* one in *Leaders in Education,* one in *International Who's Who* (Europa), and six in other directories. Of the twenty-four department heads recognized in such directories, thirteen are listed in one directory, eight in two directories, two in three directories, and one in five directories.

A summary of the subject specializations of the department heads presented in table 3 reveals that there are four areas of interest, given in order of preference: (*a*) agricultural marketing; (*b*) agricultural policy; (*c*) land and water economics, conservation, and development, and (*d*) farm management and production economics. One can relate the importance of these areas to the era in which the

[3] In the context of the *Journal* articles authored by department heads, only one department head is included in the Finley-Barger list of the thirty-eight authors most cited as referenced in the *Journal* articles during 1959–68.

individuals received their graduate training. Few department heads have specialized in the areas of statistics and methodology, econometrics, or economics of food and nutrition.

Three-fourths of the department heads are members of some professional society other than the AAEA. On the average, department heads hold membership in two professional societies in addition to their AAEA membership. Most, but not all, heads are members of the regional agricultural economics societies, the Southern Agricultural Economics Association (14), the Western Agricultural Economics Association (11), and the North Eastern Agricultural Economics Council (5). Less than one-third of the department heads are members of the American Economic Association. Seven are members of the Association of Americans for the Advancement of Science. Only one is a member of both the American Statistical Association and the Econometric Society.

One question often raised about a department head is how did he obtain the administrative position? Did he move up "through the ranks" at a given school or did he move into the position from another institution? A close scrutiny of the data provided in the *Handbook-Directory* reveals that 66% of the department heads have been promoted "through the ranks" and the remaining 34% moved into the position from another institution.

Department heads hold distinctive positions of considerable responsibility. Some have risen to become deans, while others have become presidents of universities. Some have held high government positions,[4] while others have re-entered the ranks of the faculty by preference or because of the rotating nature of the chairmanship. Although a group profile of fifty department heads presented here provides some new statistics, many questions remain unanswered. For example, what are department heads' goals and roles? What are the job requirements? What kind of administrative, research, and teaching duties do department heads perform? What kind of satisfaction do they derive from the position? How long would they recommend a person remain as a department head? What kind of conflicts arise in the line of duty between professional goals and administrative roles? Such questions have been studied by Heimler; Hill and French; McLaughlin, Montgomery, and Malpass; Satlow; and Smith.

[4] For example, Earl Butz, Secretary of Agriculture in the Ford Administration, is a former chairman of the Department of Agricultural Economics at Purdue University.

Books Reviewed

Bowers, Patricia F. *Private Choice and Public Welfare: The Economics of Public Goods*. Hinsdale, Ill.: Dryden Press, 1974, xiv + 527 pp., price unknown.

This is a truly ambitious book. It attempts to present, in a manner accessible to advanced undergraduates and beginning graduate students, a complete, coherent, and integrated account of the role of the public sector in the United States. In this one book, the reader is exposed to the broad subjects of public finance, modern welfare economics, the theory of social (or collective) choice, project evaluation techniques, static macroeconomics, macrodynamics, and the theory of stabilization policy. Specific topics include, for example, the market and efficiency, externality and public goods, the rationale for having a public sector, the optimal mix of public and private output and the optimal size of government, tax-subsidy schemes, marginal cost pricing, government influence on private choices, budget strategy, benefit-cost analysis, the economics of defense and housing, public sector budgets and fiscal incidence, the impact of government policy on saving, investment and labor market participation, employment policy, prices and incomes policy, automatic stabilizers and discretionary policy, and growth policy. Public sector activities at the federal, state, and local levels are considered as a system and the mutual influences of policies pursued at each level of government are highlighted. It is, as I have said, an ambitious book.

A subsidiary aim is to introduce the reader to the huge volume of recent literature in each of these areas. Important theoretical contributions are highlighted and applied to the analysis of specific issues. Empirical findings from the literature and government statistics are introduced, as appropriate. The economic behavior of the public sector is described, explained, analyzed, and evaluated. Mathematical analyses are presented along with verbal analyses. This reviewer has not seen another book which undertakes such a comprehensive analysis of the economics of the public sector.

It is assumed that the public sector in a market economy has four basic goals: (*a*) the provision of an environment which maximizes the scope of individual choice, (*b*) the provision of optimum [sic] levels of living, (*c*) maintenance of the optimum [sic] rate of economic growth, and (*d*) the equitable distribution of income. The integrating, analytical concept is that of public goods. Income redistribution, economic stabilization, and most everything a government provides is said to be a public good. (Bowers's definition of "public good" would seem unsatisfactory to theoretical purists, for whom the term has a more specific meaning. Not everything provided by the public sector is a public good.) The welfare concepts of Pareto-optimality and second-best optima are applied, more broadly than is usual, to evaluate not only the allocative and distributive activities of government but also macroeconomic stabilization activities.

Given the ambitious and eminently worthy goals the author has set for herself, it would be delightful to be able to praise the book wholeheartedly. However, this is a very imperfect book. It is quite poorly written, in a style which is verbose and frequently imprecise. It reads like a manuscript in search of a rigorous and fastidious editor. There are incoherent sentences, typographical errors, confusing diagrams, and diagrams which are in error. More damning, perhaps, is that the sloppiness in presentation sometimes extends to analysis. Ideas, concepts, and terminology are applied loosely. "Efficient" is often used where "effective" or "efficacious" would be more appropriate. Bowers does not seem to understand that "second-best solution" has precise meaning (the optimal feasible solution in circumstances where Pareto-efficiency is unattainable) and cannot be used to describe just any non-Pareto-efficient solution which seems workable. The concept of externality is introduced in a legal vacuum. The analysis presented on p. 97 does not prove, as claimed, that simple majority voting minimizes social costs; all it suggests is that some majority short of unanimity will probably do it.

Bowers seems sometimes to be a little too willing to accept that existing government activities are justified, in the sense that they at least make the best of a difficult situation. Regulation in externality situations, for example, is accepted with little consideration of the alternatives provided by market solutions and tax-subsidy schemes. The sentence, "[i]n fact [defense contractors] and the government work together as partners for the purpose of attaining national goals" (p. 234) seems to exhibit a touching naivete. A major omission is that the internal efficiency of government is not considered. How much of the expenditures for particular programs reach their target populations, and how much is absorbed in administrative expenses, transactions costs, etc.?

Nevertheless, there is a good deal of value in this book. The concept of an integrated analysis of the economic activities of the public sector has much to recommend it, and much of Bowers's material is adequate and competent. A major contribution is made by her several detailed examples of the interactions between different policies pursued for different purposes. The inconsistencies between targets make it difficult for government to avoid

working at cross-purposes with itself, and the student needs to understand this.

One hopes this book will appear in a second edition, in which the sloppiness and imprecision of the current edition will be eliminated. Then, Bowers's admirable concept may be executed with the clarity and rigor it deserves.

Alan Randall

Lindholm, Richard W. *Property Taxation and the Finance of Education* (TRED-7). Madison: University of Wisconsin Press, 1974, 323 pp., $10.00.

This book consists of the papers and discussion of a conference sponsored by the Committee on Taxation, Resources, and Economic Development at the University of Wisconsin. It includes contributions by distinguished researchers and leaders in the fields of economics and public finance. The purpose of the book is to examine education finance through theoretical economic analyses, empirical studies, and legal considerations.

The book first provides background material related to historical, legal, and economic issues. A brief historical perspective on financing education in the United States shows almost total dependency on local financing in the nineteenth century. As state governments recognized that some school districts lacked the taxable capacity to provide acceptable educational programs, state aid was combined with local taxation in the form of equalization programs. However, substantial disparities in educational opportunities exist among geographic regions even with increased federal and state aid. Another major criticism of the present system of education finance concerns the disparity in tax burden among local jurisdictions. Much of this criticism is focused on the property tax because it accounts for most local government revenue. Inequities in tax burdens exist partially because of an unequal distribution of industrial and commercial wealth across states. Tax inequities may also arise because of differences in community needs for taxes.

Disparities in educational opportunity and tax burdens are increasingly under scrutiny. Landmark court decisions call for substantial reform in education finance: to meet the "thorough education" standard required by New Jersey's constitution or to eliminate the fiscal disparities as required in California. The book contains several articles which explore proposed alternatives to the present finance system, including expansion of the state role within the present system, redistricting, full state funding, power equalizing, coordinated tax base sharing, and tuition grants. Power equalizing establishes a relationship between the tax rate levied and the expenditure per pupil permitted the district. Any deficiency in revenue for a given tax rate would be made up by the state so the district would achieve its permitted expenditure. With coordinated tax base sharing, states would establish a school fund to which surplus districts (based on desired tax rate and permitted revenue) would contribute and on which deficit districts would draw. Tuition grants provide publicly funded vouchers with which parents would pay some or all of their children's education.

Removal of tax impediments to equality of educational opportunity entails greater state administration of tax systems as well as increased efforts to remove tax regressivity. Several articles examine the implications of shifting tax burdens from the property tax onto other state taxes. Although heavy reliance on other taxes may create new imbalances, many possibilities for preventing such imbalances were considered. The primary reason for not abandoning the property tax as a source of revenue for education is the magnitude of new revenue that would have to be generated. Furthermore, windfall gains, which would accrue to property owners if the property tax was substantially reduced, would be generally unacceptable to the public.

Following previous books in the TRED series, this book repeatedly endorses the land tax. It is pointed out that a statewide land tax could generate revenue levels that would be comparable to the property tax and would also avoid windfall gains to some property owners. A major reason for shifting to a land tax over the property tax is that the land tax is economically neutral, while taxes on improvements are shifted to consumers, renters, etc. Although the value of land is largely created by society, land values are enjoyed by the owner and land taxes are paid by the owner. Thus, increases in the value of land which are created by society can be taxed away without decreasing general economic well-being. The unique nature of land provides a link between a tax on land and the support of education: there are elements of externalities in both the benefits of public education and the value of land.

The authors claim that alternatives to the property tax, particularly the land tax, would avoid economic distortions created by the present system of finance. They fail to measure the magnitude of the present distortions. Thus, it is difficult to properly assess the need for a complete shift away from the property tax. Also, the idea of a land tax has been popular to economists since Henry George proposed the tax, but it has been politically unacceptable. The authors fail to come to grips with this problem. Since it is doubtful that the property tax will be substantially reduced, further attention should have been focused on implications of modifying the present property tax system.

It becomes clear from reading this book that an evaluation of educational finance reform should consider the provision of all public services, not simply education. Thus, use of the local property tax to finance education cannot be considered inde-

pendently of the base's other noneducational demands and alternative nonproperty tax sources which substitute for the property taxes.

This book will be of interest and assistance to scholars in economics and public finance and to legislators, government officials, and others concerned with the role of the property tax in school finance. A major strength of the book is its breadth of coverage of alternative methods to finance education, with many excellent case studies for selected states and metropolitan areas. These analyses considered the incidence of various revenue sources and the relation of taxes paid to benefits received from education. Economic efficiency implications of the alternative tax proposals were also explored, although in less detail. On the negative side, the articles are loosely connected and sometimes repetitious.

Osofsky, Stephen. ***Soviet Agricultural Policy—Toward the Abolition of Collective Farms.*** **New York: Praeger Publishers, 1974, xi + 300 pp., $20.00.**

This is an unusual offering in policy literature. It is customary in policy to report a study of what is or has been and why. This book has this fare, too, but more. It lays out a convincing case that the viability of governments of the Soviet Union have and do hinge substantially on the course of events in the agricultural sector. In fact, it may well sketch a predictive scenario of the future. Reading along, one begins to feel the very pulse of the Soviet leadership as it grapples with an alien environment for agriculture, with unfulfilled food production plans, the troublesome kolkhoz (collective farms) as a misfit in Soviet ideology, and reconciling the propensities of the Russian peasant with the social needs of the state.

Osofsky picks up the drama. "Just as Khrushchev criticized the then state of agriculture and, by implication, his predecessor, Stalin, while announcing a 'new deal,' so did Brezhnev promise a 'new deal' for agriculture, and with much less euphemizing" (pp. 12–13). "Matskevich had been ousted by Khrushchev as Minister of Agriculture in 1960 after serving in that post since 1955. In 1960 the crop was again bad. But after Khrushchev's fall, Matskevich was reappointed USSR Minister of Agriculture in 1965 and held that post till now" (p. 240). Within six months after the famous U.S. grain sale to Russia in 1972, *Pravda* announced on its back page the dismissal of Matskevich as Minister of Agriculture, and on its front page the succession of Poliansky to that post. "It was the grain failure of 1972 that did him in, requiring as it did an offering on the altar of public humiliation."

The author continues, "If the upswing of 1973 proves ephemeral and the failures of 1972 are soon repeated, requiring grain imports on the scale of 1972, then Poliansky figures to be cast down in disgrace so as to deflect criticism away from Brezhnev. Poliansky is in a most unenviable position" (p. 242). "The Soviet leaders simply refuse to face the bedrock issues involved, and the price they will continue to pay for this is periodic grain and meat crises and a politically embarrassing dependence upon imports. Brezhnev has stumbled, just as Khrushchev did, on the seemingly intractable problem of agriculture. . . . Perhaps more than any other single domestic issue, agricultural performance will be a decisive one for Brezhnev's political future" (p. 248). With ink hardly dry on the news releases about another massive grain purchase, one waits for the next episode in the serial.

Soviet Agricultural Policy fits more the tradition of political economy found in the rich heritage of the history of economic thought than it does contemporary economics. Be that as it may, it can be a valuable reference to the policy student and teacher who explore increasingly the international dimension of agricultural policy. It may well be the best available source for contemporary Russian policy. Certainly, it supplies the most elaborate bibliography.

Osofsky sets the theme early, "The purpose of this study is to probe for the major problem areas in the kolkhoz sector rather than in Soviet agriculture as a whole, although in many cases the problems overlap and are inextricably bound together. . . . The kolkhoz problems, although certainly in good measure economic in nature, are also in part sociological and ideological. Ultimately the problems are political, and it is the political aspects that will be weighed most heavily" (p. 4). His thesis seems to be that from Stalinist times to the present, in spite of repeated policy changes and even the ray of relief afforded in Brezhnev's revisions, there still remain two temporary ideological concessions to economic expedience. The official line is that both the kolkhoz and private garden plots and livestock will die "natural deaths" just as soon as the state sector matures to the point of providing the food "cheaper and better."

The thrust of the study can be captured in a sample of its topics: Khrushchevian Legacy; The Brezhnev-Kosygin Record; the New Kolkhoz Charter (1969); Mechanization, Specialization, and Labor Problems; The Problem of a Rational Purchase Price; the Heavy Hand of Bureaucracy; the "Link" Issue (humanizing the brigade); the Private Plot and Income of Kolkhozniks; the Problem of the Optimal Size of Farms; the Land Rent and Kolkhoz Cost-Price Problem; Postscript—the 1972 Grain Deals, the Second Fall of Matskevich, and the 1973 Harvest.

This book is not for an evening of light, entertaining reading. It is for the serious student capable of following along a literary path beset wih endless

and, at times, tedious citations and a sometimes confusing organization. It stands almost as a compilation of book reviews itself and is broader than its subtitle suggests.

The fact that the author is a professor of political science diminishes not at all the value of his scholarship for students of governmental agricultural policy in the world arena.

Robert G. F. Spitze

Smith, V. Kerry. *Technical Changes, Relative Prices, and Environmental Resource Evaluation*. Baltimore: Johns Hopkins University Press for Resources for the Future, 1974, x + 106 pp., $8.00.

This monograph seeks to provide an analytical framework for linking relative price behavior, specifically increasing relative value of amenity services from natural environments, to the forces of technical change and intertemporal externalities. The framework to establish that link is outlined in a relatively systematic and concise manner contained in five short chapters (chapters 2–6) with short statements at the end of each summarizing the developments and conclusions of each stage. Both demand and supply forces which influence the relative value of amenity services and hence the allocation of environmental resources are characterized by the use of simple general equilibrium models. The monograph contains an interesting and perceptive introduction relating decisions concerning the preservation versus development of natural environments and information needed in the benefit-cost convention used to make such decisions. Chapter 2 reviews the modeling of technical change while chapters 3–6 develop the general equilibrium models used and introduce the effects of technical change and irreversibility (a specific intertemporal externality) on the supply and relative prices of fabricated goods and amenity services. The final chapter summarizes the major conclusions.

The subject covered and information obtained from the modeling effort is relevant and timely. Three legislative actions of the past decade, the Wilderness Act of 1964, the Wild and Scenic Rivers Act of 1968, and the National Environmental Policy Act of 1969, intended to protect specimens of the natural environment have brought considerable burden to analysis and evaluation of land use allocation decisions by various land management agencies. A special methodological problem arises when evaluating the benefits derived from different uses to which particular land sites may be put. The convention in benefit-cost analysis of assuming that price levels remain constant may be in error if systematic changes in relative benefits induced by differential incidence of technical change are the case. The significance of such changes in benefits has only recently been perceived in the benefit-cost evaluation of wild and scenic rivers and land sites. The author investigates those supply and demand conditions that would need to be obtained in order for goods and services, particularly amenity services of natural environments, to experience relative price appreciation due to differential incidence of technical change and intertemporal externalities.

While the general equilibrium models developed are simple and include simplifying assumptions, many of which are rather restrictive, the approach does bring us closer to being able to incorporate and trace relative price changes in the conventional cost-benefit framework. Moreover, the link between systematic changes in relative benefits, technical change, and intertemporal externalities is developed using simple neoclassical production and utility theory which should be well within the grasp of the economic analyst. Consequently, the implications of the comparative static results of the models developed can readily be explained to land use policymakers as well as stimulate application of the models to an array of preservation versus development issues. This is in contrast to much of the literature on growth and environmental quality which currently remains in the abstract.

The conclusions of the analysis that amenity services are income-elastic and few, if any, good substitutes for these services exist, and that technical change favors the supply of fabricated goods relative to amenity services, hence appreciation of the value of amenity services, are important. It is the influence of these forces that should be incorporated in the adjustments of the benefit-cost evaluation convention. Traditionally, economists and others have attempted to adjust benefit-cost estimates for inflationary or deflationary price movements, but without much success in linking these adjustments to such non-project-related forces as the effects of technical change and intertemporal externalities.

That the irreversibility effect, i.e., the presence of intertemporal externalities, decreases intertemporally the supply of amenity services and hence accentuates the appreciation of their value appears to be an oversimplified conclusion derived only from characteristics of supply. It would seem that the irreversibility effect also influences the value of amenity services through forces of demand that may be complicated by the existence of option demand. Risk and uncertainty enter to complicate the community's choice between the preservation and the development options. It would appear that the link between risk and the magnitude of the "option price" is neither direct nor one-sided, but that the prospect of transforming uncertainty to risk statements combined with the irreversibility of the development alternative induces a positive option value in favor of preservation, that is, the option value is generated by the prospect of more complete information concerning the two alternatives.

While the author's study does not present a much needed general economic theory of land use, it renders a service in extending the life of the cost-benefit convention in evaluating preservation versus development issues. The study stops short of applying the models developed to an array of cases involving decisions to develop or preserve natural environments, but does point the way to empirical study. Of course, such nasty empirical problems as measuring amenity service output, taking account of the unpriced consumption of common property resources, and more careful evaluation of technical change still exist. The book is intended to be read and understood by the economic theoretician, but the general conclusions, in simpler form, should find their way into the evaluative techniques incorporated by land management agencies and should influence more accurate evaluation of land use policy. Economists seriously intending to comprehend land use, common property, and natural resource allocation issues will find this short theoretical development useful indeed.

News

Announcements

Annual Meeting, 1976

The annual meeting of the American Agricultural Economics Association will be held August 15–18 at Pennsylvania State University in University Park, Pennsylvania. Professor James Holt is chairman of the local arrangements committee, and correspondence concerning the meeting should be directed to him. The Northeastern Agricultural Economics Council will be meeting jointly with the AAEA. A letter concerning the details of the program has been sent to all AAEA members. Further program information will be included in mailings from the local arrangements committee.

Contributed Papers for the Annual Meeting

Authors who would like manuscripts considered for the contributed papers sessions should submit the proposed titles to the chairman of the contributed papers session before May 1. Final manuscripts must be in the hands of the chairman by May 15. (This date is advanced from previous years because many members will be attending the International Association of Agricultural Economics meetings prior to the AAEA meetings.)

Contributed papers related to extension, teaching, research, or business phases of the economics of agriculture, natural resources, and rural and community development will be considered. Each author is limited to one contributed paper in which he or she is the sole or senior author. Contributions from undergraduate students are welcome.

Manuscripts should follow *Journal* manuscript guidelines (see the inside back cover of this issue). Since only twenty to twenty-five minutes will be available for the introduction, presentation, and discussion of each paper, the manuscript should not exceed twelve double-spaced pages.

Each manuscript must be accompanied by two copies of a double-spaced, fifty-word abstract. Abstracts of papers presented in the contributed papers sessions will be printed in the proceedings issue of the *Journal*, and authors should consult the December 1975 issue for the format of the abstract. Copies of the abstracts will also be available at registration and in advance of the session.

Authors of contributed papers are invited to submit their manuscripts to the editor of the *Journal* to be considered for publication. Such papers are subject to the normal review process.

The chairman of the contributed papers session is Dr. Quentin M. West, Administrator, Economic Research Service, U.S. Dept. of Agriculture, Washington, D.C. 20250.

Page Charge Policy

The AAEA Directors have voted to limit the exemptions from the page charge. Papers invited for presentation at the annual meetings and subsequent publication in the *Journal* will generally be subject to the charge. Authors should assume that the charge is applicable unless they receive explicit written exemption from the AAEA President. The revised policy statement appears inside the back cover of this issue.

NACTA Meets in Lubbock

The National Association of Colleges and Teachers of Agriculture will hold its annual meeting June 16–18, 1976, on the campus of Texas Tech University in Lubbock, Texas. The annual meeting will feature presentations on effectiveness in teaching, trends in agricultural curricula, and items of interest to teachers of agriculture. For information on the meetings, write Dr. J. Wayland Bennett, Box 4190, Texas Tech University, Lubbock, TX, 79409.

UMR-MEC Energy Conference

The University of Missouri-Rolla in cooperation with the Missouri Energy Council is sponsoring the third annual UMR-MEC Energy Conference, to be held October 12–14, 1976. The theme of this year's conference is "Energy Crises: An Evaluation of Our Resource Potential." Papers, which may be of an applied, theoretical, or interdisciplinary nature, should be submitted for review by June 1, 1976. We encourage economists from government and industry, as well as academic economists, to participate. The program chairpersons for economics are Christopher Garbacz, Vaman Rao, and William Desvousges, Economics, University of Missouri-Rolla, Rolla, Missouri, 65401.

Symposium on Animal Feeding

A symposium on "Feed Composition, Animal Nutrient Requirements, and Computerization of Diets" will be held at Utah State University, Logan, Utah, July 11–16, 1976. Internationally known scientists, representatives from industry, and government agencies from the United States and various countries in the world will participate.

Sponsored by the Committee on Animal Nutrition, National Research Council of the National Academy of Science (CAN NRC-NAS); the U.S.

Agency for International Development (AID); the International Network of Feed Information Centers (INFIC), Utah State University; and hosted by Dr. Lorin E. Harris, Professor of Animal Science and Director, International Feedstuffs Institute, Utah State University, meetings will be conducted in English, and interpreters will be available for French, German, Portuguese, and Spanish.

During the week of the symposium, five main topics will be covered. Monday, there will be meetings and discussions on feed composition; Tuesday, the subject will be nutrient utilization; Wednesday, calculating requirements of animals; Thursday, formulating diets for maximum profit; and Friday, practical system for diet formulating and animal management.

The symposium is concentrating on the use of feed composition data and nutrient requirement information in computer calculation of animal diets. Mathematical models that describe the utilization of nutrients by animals will be emphasized. The aim is to use information that describes nutrient utilization and animal requirements to produce the most profitable diet formula for animals in various physiological states and environments. Methods for solving livestock feeding and management problems will be presented.

Contact Dr. Lorin E. Harris, International Feedstuff Institute, Department of Animal Science, UMC 46, Utah State University, Logan, Utah 84322, or phone (801) 752-4100, Ext. 7424 for further information.

New Department

Under the reorganization of the College of Agriculture at Prairie View A&M University, Prairie View, Texas, a new Department of Agricultural Economics and Rural Sociology has been created. Vance W. Edmondson has been appointed head of the new department while retaining his joint agricultural economics research appointment with the Texas Agricultural Experiment Station and Prairie View A&M University, the 1890 land grant college of Texas.

Name Change

The name of the Department of Agricultural Economics at the University of Connecticut, (Storrs) has been changed to the Department of Agricultural Economics and Rural Sociology, effective July 1, 1975.

Personnel

University of Arizona

Correction: Jimmye Hillman remains as head of the Department of Agricultural Economics and is also a member of the Hazardous Materials Advisory Committee of the Environmental Protection Agency.

University of Arkansas

Appointments: James I. Martin, formerly of Virginia Polytechnic Institute and State University, is a vice president of the university; **Ralph D. May,** Ph. D. Purdue University, is an assistant professor.
Honor: H. J. Meenen, head of the Department of Agriculture and Rural Sociology, was elected president of the Southern Agricultural Economics Association for 1975–76.

University of California, Davis

Appointments: Philip L. Martin, Ph. D. University of Wisconsin, **Refugio I. Rochin,** formerly with the Ford Foundation in Bogota, Colombia, and **Barbara Zoloth,** Ph. D. University of Minnesota, are assistant professors.
Leaves: Sylvia Lane, professor, is at the Food Research Institute, Stanford University during 1975–76; **Alex F. McCalla,** professor, is on sabbatical leave but stationed at the university during 1975–76.

Canada Agriculture

Appointment: Robert W. Jolly, at work on a Ph. D. at the University of Minnesota, is with the Research Station, Bureau of Agricultural Economics, Lacombe, Alberta.

University of Chicago

Return: G. S. Tolley is back after serving as Deputy Assistant Secretary of the Treasury for Tax Policy during 1974–75.

CED: Commodity Economics Division of the Economic Research Service, USDA; **EDD:** Economic Development Division of ERS; **FDCD:** Foreign Demand and Competition Division of ERS; **NEAD:** National Economic Analysis Division of ERS; **NRED:** Natural Resource Economic Division of ERS.

Clemson University

Appointments: Larry L. Bauer, former associate professor, University of Tennessee, and **Harold M. Harris,** former assistant professor, Virginia Polytechnic Institute and State University, are associate professors; **Clayton Grant,** former associate professor, Jacksonville State University, is a visiting assistant professor.

Colorado State University

Appointment: Sam H. Johnson III is on a two-year assignment with the Water Management Research Project Field Party and U.S. Agency for International Development in Pakistan.
Return: Albert G. Madsen is back after a two-year assignment with AID.

University of Connecticut

Appointment: George A. Ecker, professor, is acting head of the Department of Agricultural Economics and Rural Sociology.

Cornell University

Appointment: T. T. Williams, professor, Southern University, is an adjunct professor.

University of Florida

Appointments: W. Arden Collette, Danny L. Gunter, and **John A. Otte** are new faculty members; **W. Kary Mathis** is director of the Agricultural Marketing Research Center.
Leave: Max R. Langham is research coordinator, Asia, for the Agricultural Development Council during 1976.

University of Georgia

Leave: Joseph C. Purcell is with the Cooperative States Research Service.

University of Hawaii

Appointments: Wen-yuan Huang, Ph.D. University of Hawaii, is an assistant professor; **J. Louis Williams,** formerly with the University of Georgia, is

an associate professor and associate extension specialist.

University of Idaho

Appointment: James R. Jones, Ph.D. University of Arkansas, is an assistant professor.

Iowa State University

Appointments: John Achterhof and **Lizardo de las Casas** are research associates in economics; **John Strauss** is a temporary assistant professor of economics.
Resignation: Richard A. Levins, former research associate in economics.

Kansas State University

Appointment: T. Roy Bogle, former area extension economist, is an extension economist in farm management.

Louisiana State University

Appointment: Sanford B. Dooley, Ph.D. Purdue University, is an assistant specialist in the Cooperative Extension Service.

University of Manitoba

Leave: Edward W. Tyrchniewicz, professor of agricultural economics, is the research coordinator for the Commission of Inquiry into Grain Handling and Transportation.

University of Maryland

Appointment: John M. Curtis, former chairman of the Department of Agriculture and Resource Economics, is the director of the state-wide Cooperative Extension Service.

University of Minnesota

Appointment: Abraham Subotnik, a faculty member at Technion, Israel Institute of Technology, Haifa, Israel, is a visiting associate professor during 1975–76.
Leave: Lee R. Martin, professor, is with AID doing research on agricultural development problems and factor analysis during 1975–76.
Resignations: Harold E. Klein, former associate professor and a member of the Minnesota team in Tunisia, is with the School of Business Administration, Temple University; **Robert M. Reeser,** former professor and a member of the Minnesota team in Tunisia, is with the Lang Engineering Corporation, Coral Gables, Florida.

Mississippi State University

Appointments: James Richard Conner, former director of Planning and Analysis for the State University System of Florida, is an associate professor and associate economist in regional economics; **Lennie G. Kizer,** former assistant professor at Pennsylvania State University, is associate professor and associate economist in agricultural financial management.

University of Missouri

Appointment: John B. Doll, chairman of the Economics Department, is the associate dean of the College of Arts and Sciences.

Montana State University

Leave: Malcolm D. Bale, assistant professor, is a visiting economist with FDCD.

University of Nebraska

Resignation: P. W. Lytle, former associate professor, is with The Andersons, Maumee, Ohio.

North Dakota State University

Appointments: F. Larry Leistritz is the associate director for social sciences to the Regional Environmental Assessment Program, Bismarck, North Dakota, on a half-time basis; **George H. Pfeiffer,** Washington State University, **Arlyn Staroba,** M.S. North Dakota State University, and **Norman Toman,** M.S. North Dakota State University, are research associates.
Leave: Robert G. Johnson is on a nine-month Fulbright Hays Fellowship at the Agricultural Institute of Economics and Rural Welfare Center, Dublin, Ireland.

Oregon State University

Appointments: John L. Ball, Jr., M.S. University of Hawaii, is a visiting assistant professor and extension marine economist during 1975–76; **Stanley F. Miller,** associate professor and director of the International Plant Production Center, is the director of a new AID grant for the development of dryland agriculture in less developed countries.

Resignation: Emery N. Castle, former dean of the Graduate School, is Senior Fellow and Vice President of Resources for the Future.

Pennsylvania State University

Appointments: Jerry A. Fedeler, formerly with Iowa State University, is an assistant professor; **Leonard Kyle,** formerly with Michigan State University, is a professor and resident economist on the Bahamas Agricultural Research, Training, and Development Project, Andros Island, Bahamas.
Leave: J. Patrick Madden, professor, is at ABT Associates, Cambridge, Massachusetts during 1975–76.

Prairie View A&M University

Appointment: Vance W. Edmondson, former associate professor at Texas A&M University, is head of the Department of Agricultural Economics and Rural Sociology.

Purdue University

Appointments: Bruce L. Brooks is a visiting professor of marketing and business management; **George F. Patrick** is an assistant professor of production economics and farm management.
Resignations: Ralph M. Brooks; Arlo J. Minden.
Leave: Joseph N. Uhl is a visiting professor at the University of California, Davis.
Honors: J. Carroll Bottum was made a Kentucky Colonel by the Society of Agricultural Farm Managers and Rural Appraisers in Lexington, Kentucky; **Wilmer A. Dahl** received the American Institute of Cooperation's 1974–75 Nourse Award for the best Ph.D. thesis on a subject related to U.S. agricultural cooperatives; **George Lee** and **Kurt Klein** received a certificate of merit for the best journal article of 1974 by the Canadian Agricultural Economics Society; **Eric C. Oesterle** received the 3rd Annual Grocers Spotlight Award; **Sam Parsons** and **David C. Petritz** won the 1975 Extension Educational Aids Blue Ribbon Award.

Rutgers University

Appointments: A. Robert Koch, head of the Department of Agricultural Economics and Marketing; **Dennis J. Palmini,** former research associate, University of Illinois, is an assistant professor.

Texas A&M University

Appointments: Dean M. Ethridge, formerly with the University of Georgia, is an assistant professor at the Marketing Research Center; **Dan Hardin,** former research assistant, Oklahoma State University, is a research associate in programming; **Charles Hodges,** former agricultural representative with a private lending institution, is a research associate at the Marketing Research Center; **Judith Houston,** former instructor of economics, Utah State University, is an assistant professor; **Ronald D. Knutson,** former administrator of the Farmer Cooperative Service, USDA, is a professor in extension, teaching, and research; **Larry C. Morgan,** former assistant professor, University of Tennessee, is an assistant professor of rural sociology and agricultural economics; **John B. Penson,** former ERS agricultural economist, Purdue University, is an assistant professor in agricultural finance.
Resignation: J. Michael Sprott, former associate professor, is the director of the Alabama Extension Service.

U.S. Department of Agriculture

Appointment: Walter L. Fishel, former associate professor, University of Minnesota, is on the program analysis and coordination staff, Agricultural Research Service.
Retirement: Harry C. Trelogan, former administrator of the Statistical Reporting Service.
Appointments in CED: Joseph Arta is with the Meat Animals Program Area; **Maury E. Bredhal,** is on the Forecast Support Staff and is an assistant professor, University of Minnesota; **O. A. Cleveland** is in Stoneville, Mississippi; **Dave Colver** is on a two-year duty tour in Korea; **Pete Emerson** is with the Office of Planning and Evaluation; **Don E. Etheridge** and **R. Samuel Evans** are with the Fibers Program Area; **Paul W. Gallagher** and **Charles Overton** are with the Forecast Support Staff; **Virden Harrison** is with the Clay Center, Nebraska; **Walter Heid** is at Kansas State University; **J. B. Penn** is in Washington, D.C.; **Dale Shaw** is in Lubbock, Texas; **Donald Van Dyne** is with the Poultry Program Area; **Mellie Warner** is with the Grains Program Area; **Glen Zepp** is with the University of Florida.
Retirement in CED: J. C. Eiland, formerly with the Grains Program Area.
Appointments in EDD: Lloyd D. Bender is the project leader, Energy Development Impact Project; **Jeff V. Conopask,** Ph.D. Virginia Polytechnic Institute and State University, is with the Analysis Program Area; **Fred K. Hines** is program area leader, Area Analysis Program Area; **Ronald W. Holling** is with the Manpower Studies Group; **Thomas A. Sachs** and **William Sinclair** are with the State and Local Government Program Area.
Appointments in NEAD: Burl Back is head of a special project, Food and Fiber Program Area; **Arvin R. Bunker** is with the Transportation Economic Program Area; **Susan Cobb** is with the Consumer Interest Program Area; **Floyd D. Gaibler** is with the Transportation Economics Program

Area; **George St. George** is with the Demand Analysis Program Area; **James Schwinden** is with the Transportation Economics Program Area.
Retirement in NEAD: William H. Scofield.

Virginia Polytechnic Institute and State University

Appointment: James D. Dean, B.S. Ohio State University, is a research associate.

Washington State University

Appointment: Gayle S. Willett, formerly with the University of Arizona.

University of Wisconsin

Honor: Douglas Yanggen received the Soil Conservation Society of America's Commendation Award in recognition for his work on the legal and economic aspects of land use.

University of Wyoming

Appointment: James J. Jacobs, Ph.D. Iowa State University, formerly with NRED, Cornell University, is an associate professor.

Other Appointments

Salem Gafsi, Ph.D. University of Minnesota, is with the International Bank for Reconstruction and Development.
Joseph Howard Gill, M.S. Purdue University, is an extension agent, Cooperative Extension Service, Lafayette, Indiana.
Kenneth L. Graber, M.S. Purdue University, is an agricultural missionary, Board of Global Ministries, United Methodist Church, Cochabamba, Bolivia.
Ioannis Karmokolias, Ph.D. Virginia Polytechnic Institute and State University, is with James R. Leonard Associates, Washington, D.C.
George Lee, formerly with Purdue University, is an associate professor, University of Saskatchewan.
Clarence J. Miller is the UN E.C.A. regional advisor in Addis Ababa, Ethiopia.
Sang-Woo Park, Ph.D. University of Minnesota, is with the Ministry of Agriculture and Fisheries Division of General Affairs, Seoul, Korea.
William B. Riley, Jr., Ph.D. University of Arkansas, is an assistant professor of business administration, St. Cloud State University.
Donnie A. Smith, M.S. University of Arkansas, is a county extension agent, Cooperative Extension Service, Jonesboro, Arkansas.
John Shipley Young, M.S. Purdue University, is vice president of Melrose Farms, Herndon, Kentucky.

Obituaries

John Lossing Buck

John Lossing Buck, the builder of the Department of Agricultural Economics at the University of Nanking, China and its head for two decades, died September 27, 1975, two months prior to his 85th birthday.

Buck went to China in 1915 as an agricultural missionary in Anhwei Province, 200 miles north of Nanking. Five years later, the University of Nanking invited him to join its faculty and to initiate work in agricultural economics. It was here that he introduced the discipline to China in all its aspects: teaching, research, and public service. Perhaps his greatest accomplishment was inspiring and training young Chinese in this new field of study. In less than two decades, these young men under Buck's leadership built one of the largest and strongest departments in the College of Agriculture and the only significant program in agricultural economics in China. The Sino-Japanese War interrupted academic life and forced the university to move first to Hankow and later to Chengtu in western China.

Dr. Buck trained his students in methods of obtaining economic information where little or none existed. They learned how to collect data systematically in the field, analyze them, and organize the results for publication. His group undertook short-run crises projects occasioned by floods and famine and was recognized by public officials as a dependable source of useful information. The group also undertook more traditional studies of farm management, cooperatives, marketing, land use, and prices. Buck was a pioneer at institution building in an underdeveloped country.

After the war, Buck left China but returned for several months in 1946 as a member of the China-United States agricultural mission under the auspices of the U.S. Department of Agriculture. Later he served as chief of the Land and Water Use Branch of the Food and Agriculture Organization of the United Nations. In 1954, he returned to the United States and was director of agricultural economics for the Council of Economic and Cultural Affairs (now the Agricultural Development Council) until he retired in 1957.

In his first book, *Chinese Farm Economy*, published in 1930, he reported on a study of 2,866 farms in seventeen localities in China. He later authored *Land Utilization in China*, a three-volume report of a massive survey of the whole of rural China published by the University of Chicago Press in 1938. In 1973, he wrote *Development of Agricultural Economics at the University of Nanking, Nanking, China, 1926–1946*, which was published as Cornell International Agricultural Development Bulletin No. 25.

Buck was born at Pleasant Valley, New York on November 27, 1890. He received the B.S. degree in 1914, M.S. in 1925, and Ph.D. in 1933, all from Cornell University. Buck's first marriage to the late Pearl S. Buck ended in divorce in 1935. He later married Lomay Chang who survives him, as does a son, Paul, and a daughter, Rosalind Lewis. He is also survived by two daughters of his first marriage, Carol and Janice.

George L. Capel

George L. Capel, assistant director of the North Carolina Agricultural Extension Service, died in Raleigh, North Carolina, October 7, 1975.

Capel was born in Garysburg, North Carolina in 1923. He attended North Carolina State College prior to World War II. He served as a naval officer during the war. He returned to North Carolina State University and received a B.S. degree in agricultural economics in 1948 and an M.S. in 1949. Capel was then employed by the Farmer Cooperative Service in Washington, D.C. He transferred to Gainesville, Florida and the BAE in 1952, where he worked on fruit and vegetable marketing problems. He received a Ph.D. from the University of Florida in 1956. In 1961, he returned to North Carolina State University as specialist in Charge of Extension Marketing Programs. In 1968, he was promoted to assistant director of the Agricultural Extension Service.

In addition to his work, George Capel devoted his considerable talent and skills to his community, his church, and above all his family. He served the American Agricultural Economics Association as a member of the Publications Awards Committee from 1972–75.

To those who knew him, it was the sheer joy of being in his presence, anywhere or any time, that will be remembered. He was a man of uncommon wit and humor. He was also a gentle person. The combination made George Capel an absolutely delightful colleague, friend, or supervisor. Those who knew him will not soon forget him.

He is survived by his widow Marie, son James, and daughter Gail.

Dennis E. Crawford

Dennis E. Crawford, 61, associate professor at Clemson University, died unexpectedly at his home August 5, 1975.

Crawford was a native of Clemson, South Carolina, and received both his B.S. and M.S. de-

grees in agricultural economics from Clemson. He came to work with the Department of Agricultural Economics and Rural Sociology in 1936 and has been employed by the department continuously since that time, except for a seven-month period in 1943 when he was employed by the Soil Conservation Service, U.S. Department of Agriculture.

During his career, Crawford's research interests included numerous areas in farm management and agricultural marketing. Over the last several years, he had studied trends in the use of cotton and competing fibers, the costs of cotton ginning, the availability and use of agricultural credit, the economics of caged-layer egg production, and the economics of hay harvesting and handling systems. Most recently, he was engaged in development of farm enterprise budgets by computer for use in extension farm management programs. Perhaps his greatest contributions to the programs of the university, however, arose from his detailed knowledge of where needed publications and information were located, and in his matchless skill in obtaining cooperation among diverse individuals and groups. He made his knowledge and services available for the asking to associates and students in the department, college and university, and to many others.

He is survived by his wife, Anne, a daughter and a son, as well as a brother and a sister.

Perry Virgil Hemphill

Perry Virgil Hemphill died on March 8, 1975 near Tucson, Arizona at the age of 79. He is survived by his wife, Martha, a son, Harlan, and several grandchildren.

Hemphill was born in Partridge, Kansas on June 12, 1896. He received his B.S. and M.S. degrees from Colorado State University in agricultural economics. After completion of his M.S. degree, he taught high school and then worked as an agricultural economist for several federal agencies. Perry came to North Dakota Agricultural College as an Extension Grain Marketing Specialist in 1937. He began his teaching career in 1942, when he became an assistant professor of agricultural economics. He moved up the ranks and held the rank of professor of agricultural economics at North Dakota State University when he retired in 1967. During the 1954–55 year, he was acting chairman of the department.

Perry V. Hemphill is best remembered by people who were associated with him as a dedicated teacher and researcher. Those who worked with him or had him as an adviser or instructor remember him best as one who gave untiringly of his time and talents to all who came to him. He was always willing to listen to a student's problems and counsel him in his career decisions. His wisdom, kindness, and good judgment touched the lives of thousands of people during his long career.

All who had the privilege of knowing Perry V. Hemphill were deeply saddened by his untimely death in an automobile accident, which also took the lives of his son, Eldon, and Eldon's wife near Tucson on March 8, 1975. Perry's wife, Martha, survived the accident and resides in Elkhorn, Iowa.

PRODUCTIVITY TRENDS IN A SECTORAL MACRO-ECONOMIC MODEL:

A Study of American Agriculture and Supporting Industries, 1919-1964

(Monograph Series #1)

Price: $25.00 (U.S. Funds).
pp. 296 + xxii, Figs. 26, Cloth M8;
ISBN 0 904870 03 0; 9/72;

CONTENTS: Introduction; I: The Case for the Sub-system; II: Sub-systems simply explained; III: Productivity measures in the context of the Sub-system; IV: Application of Macro-economic analysis to sub-systems; V: Extensions of such applications; VI: The Agricultural Sub-system's Past & Future Technical Progress; VII: Conclusions. *Appendices:* A,B: Mathematical Proofs and Addenda; C: Data; D: Dovring Indices; E: Agricultural Index Numbers; F: Input-Output Concordance Tables; G: Employment and Capital Components for the Agricultural Sub-system. Bibliography.

LAND ECONOMICS

Land Economics is a scholarly journal devoted to the study of land, which in Alfred Marshall's words is, "the material and the forces which nature gives . . . for man's aid, in land and water, in air and light and heat."

Founded in 1925 as a journal of resources and utilities, *Land Economics* is now returning to its original emphasis on articles which either address the determinants and consequences of economic activity on the value and use of land, or the contribution of natural and environmental resources to economic activity. Emphasis is placed on both empirical and theoretical work designed to explore these relationships between land and the economy.

The Economics Institute

Announces its 19th Annual Program for

International Students

IN ECONOMICS AND RELATED FIELDS

UNIVERSITY OF COLORADO, Spring and Summer of 1976

MAIN PROGRAM (Summer) JUNE 7-AUGUST 18 or JULY 12-AUGUST 18

preceded by a special

INTENSIVE ENGLISH PROGRAM (Spring) with multiple entry dates of January 19, February 23, March 29 and May 3

The Institute specializes in transitional academic preparation for graduate work in economics and related fields, including business and agricultural economics, and short-term professional upgrading for specialists in these areas.

Its *Main Program* in the summer provides concentrated instruction tailored to individual needs through appropriate combinations of course work in

- ECONOMIC THEORY
- MATHEMATICS
- ENGLISH
- STATISTICS

complemented by lectures and seminars in

ECONOMICS, BUSINESS, AGRICULTURAL ECONOMICS, AND DEVELOPMENT

The *Intensive English Program* offered during the spring provides an opportunity for applicants with lower levels of proficiency in English to improve their language skills prior to the summer and thereby to qualify for a larger selection of course offerings in other areas in the main session. The spring program has multiple entry dates to accommodate varying language preparation needs and training schedules.

Field trips and social and recreational activities are included to acquaint participants with campus and community life in the U.S.A. Intercultural activities further enrich the program.

Further information and application materials may be obtained from the Director, Economics Institute, University of Colorado, Boulder, Colorado 80309, U.S.A.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter to the editor, the author must state (*a*) that the material has not been published, and is not being published or being considered for publication elsewhere; (*b*) that the material in the manuscript, so far as the author knows, does not infringe upon other published material protected by copyright; and (*c*) that he or she is aware that each issue of the *Journal* is copyrighted, that submission of a manuscript to the *Journal* gives the AAEA the right to publish and to copyright the material, and that republication elsewhere at a later date is contingent upon written approval from the *Journal* editor. If the applicability of point (*a*) is unclear, the author should provide an explanation of the publication status of the manuscript.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Review by colleagues.** Authors are strongly urged to have their manuscripts critically reviewed by their colleagues prior to submission.
12. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
13. **Page Charge.** All published contributions, with certain specific exemptions, are subject to a charge of $40 per printed page or fraction thereof. Exemptions are granted for book reviews, papers invited by the editor, the presidential address, the fellow's lecture, and those invited addresses and papers receiving explicit written exemption from the AAEA president. Authors who certify in writing that no financial support exists from an employer or granting agency to cover the page charge also will receive an exemption. Payment information and details on the financial exemption statement are provided with galley proofs. One hundred reprints (without covers) are provided if the charge is honored.

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—publishing the *American Bibliography of Agricultural Economics* and supporting an associated retrospective literature search in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

The subscription rate for institutions and nonmembers is $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal,* changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics*.

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices.

Copyright © 1976 by the American Agricultural Economics Association.

An article, note, or other material appearing in the *American Journal of Agricultural Economics* may not be republished in full or in part without the express written permission of the editor.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except that concerning "Books Reviewed" and "Books Received," should be addressed to the editor, William G. Tomek, Department of Agricultural Economics, Cornell University, Ithaca, New York 14853.

Communications concerning books for review and books submitted for announcement in the *Journal* should be sent to the book review editor, Francis E. Walker, Department of Agricultural Economics and Rural Sociology, Ohio State University, Columbus, Ohio 43210.

The Impact of Increasing Food Supply on Human Nutrition: Implications for Commodity Priorities in Agricultural Research and Policy

Per Pinstrup-Andersen, Norha Ruiz de Londoño, and Edward Hoover

A procedure is developed to estimate the nutritional implications of alternative commodity priorities in agricultural research and policy. The model estimates the distribution of supply increases among consumer groups, the related adjustments in total food consumption, and implications for calorie and protein nutrition. Findings from an empirical application of the model to the population of Cali, Colombia, suggest that relative increase in total nutrient supply is a poor indicator of relative nutritional impact because both nutritional waste and consumer adjustment in total food consumption are a function of the commodity from which the additional nutrients are obtained.

Key words: agricultural research priorities, human nutrition, income distribution, price elasticities, research resource allocation.

Malnutrition, primarily calorie and protein deficiencies, has been widely recognized for some time as a serious problem among low income groups of the population of many developing countries. However, only recently has improved human nutrition become an important part of development goals in most of these countries. As more emphasis is placed on equity and welfare in overall development plans, improved nutrition is gradually being accepted by government planners and politicians as a worthwhile goal in itself. Furthermore, the importance of health and nutrition for human capital formation and the resulting implications for economic growth has gained wide recognition during recent years. As a result, activities with the direct aim of expanding food production, such as certain agricultural research and public policy, frequently consider improved human nutrition as one of their final goals.

Although the immediate objective of production-oriented agricultural research and public policy may be to expand food production, such an objective may be viewed as a means to reach some set of final goals, one of which possibly being improved human nutrition. The challenge to the decisionmaker in production-oriented research and policy then becomes one of choosing among alternative strategies to attempt to maximize the contribution to the final goals for any given amount of resources available. For this purpose, information is needed on expected relative contribution of alternative strategies to the achievement of specified goals and on program and associated costs of each alternative.

Little is known about the relative nutritional impact of alternative agricultural research and policy strategies. There is a tendency to consider the increase in total nutrient supply as a measure of the improvement in human nutri-

Per Pinstrup-Andersen is director of the Agro-Economic Division of the International Fertilizer Development Center, Florence, Alabama; Norha Ruiz de Londoño is a research assistant at Centro Internacional de Agricultura Tropical, Cali, Colombia; and Edward Hoover is a graduate student in the Department of Systems and Industrial Engineering at the University of Arizona.

The authors are grateful to James Cock, Alain de Janvry, David Franklin, and Grant Scobie for valuable comments on an earlier draft of this article.

tion. But increases in nutrient supply will make a positive contribution to human nutrition only if the consumer is deficient in the particular nutrient in the absence of the supply increase. Nutrient supply increases of equal magnitude but originating from different commodities may have different impacts on human nutrition because the distribution of the additional supply among consumer groups differs. Hence, to establish commodity priorities in research and policy aimed at expanding food production for the purpose of improving human nutrition in the most effective way, it is essential to estimate not only expected increases in nutrient supply but also what proportion of the supply increase will be consumed by deficient consumer groups and the resulting adjustments in the consumption of other foods.

Production-oriented agricultural research and policy is frequently commodity specific and priorities need to be established at two levels, choice of commodities and choice of activities within commodities. Ramalho de Castro and Schuh developed and empirically tested methodology that would assist in establishing commodity priorities in research on the basis of expected distribution of benefits between producer and consumer sectors and among factors of production within the producer sector.

The purpose of this paper is to indicate an approach to economic analysis that may help establish commodity priorities in agricultural research and public policy if improved human nutrition is a goal. Thus, the paper supplements the Ramalho and Schuh methodology by providing a means for estimating the distribution of supply increases among urban consumer groups and the resulting nutritional benefits. The issue of criteria for establishing priorities between improved urban nutrition and other goals is not treated.

A model is developed to estimate the nutritional impact of expanding the supply of any one of the foods currently available to the consumer.[1] On the basis of this model, an empirical analysis is carried out with sample data from Cali, Colombia. This paper presents the model, briefly describes the data requirements and sample characteristics, summarizes the empirical findings, and discusses the utility and limitations of the model for establishing nutrition-oriented priorities in agricultural research and public policy.

[1] Only the nutritional impact due to change in calorie and protein intakes is considered in the model. Possible impact due to changes in other nutrients and interactions among nutrients is ignored.

The Model

The model is based on neoclassical demand theory. It is presented in two parts, the first referring to the estimation of a price elasticity of demand matrix for each of a number of income strata and for the market as a whole and the second dealing with the distribution of a hypothetical supply increase of any one good among these income strata, the resulting adjustments in consumption of all other goods, and the impact on calorie and protein nutrition.

Price Elasticity Matrix

A complete price elasticity of demand matrix was estimated for each of the income strata using the methodology developed by Frisch. Assuming want independence among the commodities or groups of commodities considered, Frisch provides a method for estimating a complete set of direct and cross price elasticities of demand on the basis of income elasticities, budget proportions, and the flexibility of money.

Let $\phi = \frac{\partial w}{\partial a}\frac{a}{w}$ be the flexibility of money, where w is the marginal utility of money income and a is money income. Then, the direct and cross price elasticities of demand for income stratum m may be estimated as

$$(1)\quad e_{ii(m)} = -E_{i(m)}\left[A_{i(m)} - \frac{1 - A_{i(m)}E_{i(m)}}{\phi_{(m)}}\right],$$

and

$$(2)\quad e_{ij(m)} = -E_{i(m)}A_{j(m)}\left[1 + \frac{E_{j(m)}}{\phi_{(m)}}\right],\ i \neq j,$$

respectively, where e_{ii} is the direct price elasticity of demand for good i, e_{ij} is the cross price elasticity for good i with respect to good j, E_i and E_j are the income elasticities for goods i and j, respectively, and A_i and A_j are the budget proportions spent on goods i and j.

Assuming that all consumers are faced with the same market for any one commodity, the average per capita direct and cross price elasticities of demand for good i was estimated as the weighted average of the strata elasticities using quantity of good i consumed by stratum

m and relative proportion of total population found in stratum m as weights:

$$(3) \qquad e_{ij} = \frac{\sum_{m=1}^{n} e_{ij(m)} Q_{i(m)} N_{(m)}}{\sum_{m=1}^{n} Q_{i(m)} N_{(m)}},$$

where $e_{ij(m)}$ = direct or cross price elasticity of demand for stratum m, $Q_{i(m)}$ = quantity consumed per capita of commodity i in stratum m, and $N_{(m)}$ = population of strata m.

The assumption of want independence implies that the marginal utility of one good is independent of the quantity consumed of any other good for which want independence is assumed. Hence, if want independence is assumed for all goods, direct additivity of the utility function is implied, i.e., $u(q_1, q_2, \ldots, q_n) = u_1(q_1) + u_2(q_2) + \ldots + u_n(q_n)$ (George and King, p. 23). However, the goods are still related through the budget constraint; hence, want independence does not imply the much stronger assumption of demand independence. Although some goods, such as electricity and Swiss cheese, can safely be regarded as want independent, as argued by Frisch, the assumption is obviously not valid for all goods. It may be possible, however, to group the bundle of goods available to the consumer to obtain little or no want independence among groups (Bieri and de Janvry). Where this is possible, the Frisch scheme may then be applied to estimate group elasticities. Assuming that the consumer budget is first allocated among such groups and then the amount allocated to each of these groups is allocated to individual goods within the particular group, the two-stage maximization process may provide elasticity estimates for the individual goods (de Janvry, Bieri, and Núñez). However, in addition to the cross-section data needed to estimate income elasticities, time-series data are needed to estimate price elasticities. The applicability of the two-stage maximization process is limited because of the scarcity of reliable time-series data. Such scarcity is particularly pronounced in cases where elasticities are needed by income strata.

No reliable time-series data on prices and quantities were available for the present study. Hence, the two-stage process could not be applied. On the other hand, since the primary purpose of the study was to develop and empirically test a methodology for estimating the nutritional impact of supply expansions and not to estimate price elasticities per se, it was felt that direct application of the scheme developed by Frisch would provide sufficiently accurate elasticity estimates. This supposition was supported by the actual estimates obtained, all of which fall within expected magnitudes. However, the assumption of want independence is not likely to be valid for all goods considered; hence, the empirical results of this study should be interpreted with caution.

Change in Calorie and Protein Intakes

This part of the model quantifies the change in calorie and protein intakes by income strata caused by an externally introduced shift in the supply curve of any one of the food commodities or groups of food commodities considered. The model estimates the distribution among strata of the additional supply of the food for which the supply curve is shifted and the resulting adjustments in the consumption of all other foods and consists of a set of recursive equations. Assuming that all consumers are faced with the same market in which perfect competition exists and that prices and quantities for all foods are in equilibrium before the shift in the supply curve, the model estimates the new equilibrium for prices and quantities for all foods utilizing an iterative procedure.[2]

If the initial market equilibrium price for commodity i is P_i^o, the new equilibrium price P_i^1 after shifts in the supply and/or demand curves is estimated as (Pinstrup-Andersen and Tweeten, p. 538)

$$(4) \qquad P_i^1 = P_i^o \left[1 - \frac{\Delta S_i - \Delta D_i}{(e_{si} - e_{ii})\, Q_i^o} \right],$$

where ΔS_i = horizontal shift in supply curve of commodity i, ΔD_i = horizontal shift in demand curve of commodity i, e_{si} = price elasticity of supply for commodity i, e_{ii} = market price elasticity of demand for commodity i, and Q_i^o = initial equilibrium quantity of i.

Using a similar procedure, the new equilib-

[2] The model is static in the sense that no shifts in the demand curves can occur except those due to changes in prices of other goods brought about by the initial shift in the supply curve and subsequent adjustments, i.e., consumer incomes, tastes, preferences, and other potential demand shifters are assumed constant.

rium quantity of commodity $i(Q_i^1)$ is estimated as

$$(5) \quad Q_i^1 = Q_i^o + \Delta D_i + \frac{\Delta S_i - \Delta D_i}{1 - (e_{si}/e_{ii})}.$$

Applying these two equations, the change in price and quantity of commodity i due to an externally introduced shift in the supply curve (and no change in the demand curve) is estimated as

$$(6) \quad P_i^k = P_i^{k-1}\{1 - [B/(e_{si} - e_{ii})]\},$$

and

$$(7) \quad Q_i^k = Q_i^{k-1}\{1 + B/[1 - (e_{si}/e_{ii})]\},$$

where $k = 1$, and $B = \frac{\Delta S_i}{Q_i^{k-1}}$ = the horizontal shift in supply curve as a proportion of initial quantity.

The final equilibrium price and quantity would be P_i^1 and Q_i^1 for good i if, respectively, $e_{ji} = 0$ or $e_{ij} = 0$ for all $j \neq i$ where e_{ij} is the cross price elasticity of demand for commodity i given a change in the price of j. Furthermore, if $e_{ji} = 0$ for all $j \neq i$, the equilibrium prices and quantities for all other commodities would remain unchanged. However, neither e_{ji} nor e_{ij} can be expected to equal 0. Hence, the initial change in P_i will cause a shift in the demand curve for all other commodities (j). The resulting new equilibrium prices (P_j^1) and quantities (Q_j^1) are

$$(8) \quad Q_j^k = Q_j^{k-1}\{(1 + p_i e_{ji}) [1 - (1 - e_{sj}/e_{jj})^{-1}]\},$$

and

$$(9) \quad P_j^k = P_j^{k-1}(1 + p_i e_{ji})/(e_{sj} - e_{jj}),$$

where $k = 1$, $p_i = (P_i^k - P_i^{k-1})/P_i^{k-1}$, and $j = 1, \ldots, 22$ excluding $i, j \neq i$.

The changes in prices and quantities of j, i.e., commodities different from commodity i, cause a shift in the demand curve for commodity i unless $e_{ij} = 0$ for all j. The new equilibrium price and quantity for i is given by

$$(10) \quad Q_i^k = Q_i^{k-1}\{1 + \sum_{j=1}^{n} p_j e_{ij} [1 - (1 - e_{si}/e_{ii})^{-1}]\},$$

and

$$(11) \quad P_i^k = P_i^{k-1}\left[1 + \sum_{j=1}^{n} p_j e_{ij} (e_{si} - e_{ii})^{-1}\right],$$

where $k = 2$ and $p_j = (P_j^1 - P_j^o)/P_j^o$, $j \neq i$, $j = 1, \ldots, 22$ excluding i. This iterative procedure continues by replacing the current value of superscript k by $k + 1$ until a steady state is reached ($k = F$), i.e., equilibrium for price and quantity for all commodities. In the empirical analysis discussed later, the steady state for most commodities was reached for $k \leq 3$.

Having estimated the new market equilibrium, the model proceeds to estimate the distribution among strata of the quantity changes for each commodity. The final quantity of commodity j obtained by stratum m ($Q_{j(m)}{}^F$) is

$$(12) \quad Q_{j(m)}{}^F = N_{(m)} N^{-1} Q_{j(m)}{}^o [1 + p_i' e_{ji(m)} + p_j' e_{jj(m)}],$$

where $j = 1, \ldots, 22$ excluding i; $m = 1, \ldots, 5$, $i \neq j$, $N_{(m)}$ = number of consumers in stratum m, N = total number of consumers, and $P_i' = (P_i^F - P_i^o) / P_i^o$.

The final quantity of commodity i obtained per capita in stratum m ($Q_{i(m)}{}^F$) is given by

$$(13) \quad Q_{i(m)}{}^F = Q_{i(m)}{}^o\left[1 + \sum_{j=1}^{n} p_j' e_{ij(m)} + p_i' e_{ii(m)}\right],$$

where $j \neq i$.

The direct impact on per capita calorie $C_{i(m)}$ and protein $PR_{i(m)}$ intake in stratum m is estimated as

$$(14) \quad C_{i(m)} = [Q_{i(m)}{}^F - Q_{i(m)}{}^o]\, c_i,$$

where c_i = calorie content per unit of commodity i, and

$$(15) \quad PR_{(m)} = [Q_{i(m)}{}^F - Q_{i(m)}{}^o]\, pr_i,$$

where pr_i = protein content per unit of commodity i.

The indirect impact is

$$(16) \quad C_{j(m)} = \sum_{j=1}^{n} \left[Q_{j(m)}{}^F - Q_{j(m)}{}^o\right] c_j,$$

and

$$(17) \quad PR_{j(m)} = \sum_{j=1}^{n} \left[Q_{j(m)}{}^F - Q_{j(m)}{}^o\right] pr_j,$$

where $j \neq i$. The net impact is

$$(18) \quad C_m = C_{i(m)} + C_{j(m)},$$

and

$$(19) \quad PR_{(m)} = PR_{i(m)} + PR_{j(m)}.$$

Data Sources and Sample Characteristics

Data on quantities consumed and prices paid for each of twenty-two foods or groups of food

Table 1. Selected Descriptive Characteristics of the Sample Families

	Strata				
	I	II	III	IV	V
Income range ($/family/month)	0–42.4	42.5–56.5	56.6–113.0	113.1–169.5	169.6–up

Number of persons in families interviewed	270	264	544	201	200
Distribution of persons on strata (%)	18.3	17.8	36.8	13.6	13.5

as well as family incomes, size, and age distribution were collected from a sample of 230 families selected from the population of Cali, Colombia, using a stratified random sampling procedure. Each family was visited during February 1969, and again in August 1970.[3] For various reasons, about 30% of the families included in the first survey could not be included the second time. These families were replaced in the sample by randomly selected families living in the same part of town. Five strata were established on the basis of family incomes and the sample size for each stratum was proportional to the population among strata. Table 1 shows selected characteristics of the sample families.

Empirical Results

Income Elasticities and Budget Proportions

The income elasticity for each food was estimated for each of the five income strata on the basis of cross-section data within each stratum. The consumers within each stratum were faced with essentially the same price for any given food commodity. Furthermore, little variation in tastes and preferences was expected among consumers within a given stratum. Hence, the income elasticities were estimated simply by regressing per capital real income on per capita quantity consumed within each stratum. The estimated income elasticities were consistent with expectations. Foods of animal origin ("luxury goods") tended to have higher income elasticities than staple foods. All the foods showed a decreasing income elasticity for increasing incomes, becoming negative for certain staples in high income strata. The methodology used to estimate price elasticities is only valid for nonnegative income elasticities. Hence, where negative estimates did occur, a value of zero was used for estimating price elasticities, resulting in zero-value price elasticities.

Beef, accounting for 10%–12% of total incomes in all strata, was the largest single food expenditure for all strata. The budget proportion spent on most of the other food items decreases for increasing incomes. In addition to beef, basic grains, primarily rice, maize, and beans, account for a considerable amount of the consumer budget particularly in the low income strata. Tables showing income elasticities and budget proportions may be obtained directly from the authors.

Money Flexibility

Bieri and de Janvry report a number of estimates of the flexibility of money for various countries and time periods. These estimates range from −0.61 to −3.90. No such estimate

[3] The first survey was conducted by a Michigan State University marketing research team headed by Kelly Harrison. Upon completion of the project, the team kindly made data useful for the present study available to CIAT. The second survey was conducted by CIAT. Results of the MSU analyses and a detailed explanation of sampling procedures are reported by Riley et al.

was available for Cali or Colombia either for the population as a whole or by income strata.

Solving equation (1) for ϕ we get

$$\phi = \frac{E_i\,[1 - A_i\, E_i]}{e_{ii} + A_i\, E_i}. \tag{20}$$

The flexibility of money can be estimated on the basis of the income elasticity and the direct price elasticity for one good and the budget proportion spent on that good. No reliable estimate of price elasticities by income strata for Cali was available prior to this study. Hence, to estimate ϕ by income strata it was necessary first to estimate e_{ii} for at least one good for each income strata using an alternative method.

As explained above, data on quantity consumed, prices, and incomes were collected from the sample households for two points in time. Six highly standardized food commodities (rice, beans, tomatoes, oranges, sugar, and cooking oil) were chosen for a priori estimation of direct price elasticities. The change in quantity consumed and price for each of these foods between the two surveys and the change in incomes were estimated for each income strata. The change in quantity consumed was assumed to be due exclusively to changes in a product's own price and incomes.

The expected impact of income change on consumption was estimated on the basis of the income elasticity estimates from cross-section data and the remaining change in consumption was attributed to price change, thus providing an estimate of direct price elasticity. This procedure for obtaining a priori estimates of direct price elasticities is somewhat crude, primarily because no cross price effects were considered. However, we may assume that cross elasticities are small, although not zero. Hence, it was felt that the approximations of actual direct price elasticities provided by the procedure were sufficiently good—and certainly the best available, given the data constraints—for the purpose of estimating money flexibility. Furthermore, the fact that all a priori estimates fall within expected ranges for the particular commodities indicates considerable confidence in the method.

Using equation (20), the flexibility of money was estimated for each income strata as a simple average of the estimates obtained from each of the six food commodities (table 2). No significant difference of the estimated ϕ among strata was found.[4] The magnitude of ϕ as estimated here is similar to estimates from Chile for the period 1952–63 and the United States for the period 1923–41 and 1948–56, while it is considerably below estimates from Argentina and certain other countries (Bieri and de Janvry). In general, the estimated ϕ is below what would be expected on the basis of most previous estimates for other countries. Furthermore, the estimates are inconsistent with Frisch's conjecture that the absolute value of ϕ decreases as the level of real income increases. This study does not provide an acceptable explanation for this inconsistency but points out the need for additional empirical study on the relationship between ϕ and income levels within a given society. De Janvry, Bieri, and Núñez found a statistically significant fit when regressing estimates on ϕ from various countries and time periods on real incomes using a constant elasticity equation. However, such intercountry comparisons, although highly useful, suffer from the usual problems of choosing exchange rates that reflect real differences in purchasing power. Furthermore, intercountry differences in preferences not due to income levels are likely to influence marginal utility of money and the magnitude of the money flexibility. Hence, at equal real incomes, the money flexibility is likely to differ among countries. Correlation among countries, between preferences on the one hand and income levels on the other, may bias the results of intercountry comparisons.

[a] Weighted average using total quantity consumed by strata as weights.

(Complete direct and cross price elasticity matrices may be obtained from the authors.) All estimates fall within expected ranges. As would be expected, the direct price elasticity for all goods increases for increasing income, and a considerable difference between the elasticity estimated for high income groups and that for low income groups was found for most commodities.

Nutritional Implications

The model shown by equations (6) through (19) was run for a hypothetical shift in the supply curve for each of the twenty-two commodities considered ($i = 1, \ldots, 22$), keeping the supply curves for the other twenty-one commodities constant. A horizontal shift in the supply curve equal to 10% of current supply of commodity i was arbitrarily selected, and the resulting net effects on protein and calorie intakes were estimated. No reliable estimates of the price elasticities of supply were available for the twenty-two commodities. It may be expected, however, that the supply elasticity is close to zero in the short run for most of the commodities, while it is likely to be larger but less than one for the intermediate and long run.[5] Supply elasticities equal to 0, 1, and 2 for all commodities were chosen for estimation. Although the absolute impact of a shift in the supply curve of a certain commodity on net calorie and protein intakes is sensitive to the magnitude of the supply elasticities, the relative impact among commodities does not depend greatly on the magnitude of the supply elasticities. Hence, since this study is primarily focused on relative impacts, the choice of supply elasticity is of little importance, as will be shown in the final part of the paper.

Indicators used to estimate the nutritional impact of shifting the supply curve of each of the commodities are the percentage of the total supply increase of commodity i consumed by nutrient deficient income strata, the change in per capita calorie and protein intake by deficient strata, and the percentage reduction in total calorie and protein deficiencies.

[5] The short run is defined here as the period not exceeding that occurring between production decision and the resulting impact on supply.

Table 4. Estimated Calorie and Protein Intakes and Deficit or Excess by Strata

	Strata					
	I	II	III	IV	V	Average
Estimated daily intake of calories per capita	1904	2119	2510	2831	3836	2552
Intake of requirements (%)[a]	89	99	117	132	178	119
Estimated daily intake of protein per capita (g.)	44.6	51.6	64.6	81.1	126.4	69.2
Intake of requirements (%)[a]	72	83	104	131	204	112

[a] Based on estimated requirements for Colombia (Williamson, Parra, and Téllez).

As shown in table 4, two of the five strata are deficient in protein and one is deficient in calories. Assuming that changes in nutrient intakes influence nutrition only if a nutrient deficiency exists—either before or after the change, increased or decreased protein and calorie intake influences nutrition if it occurs in strata I and II and stratum I for protein and calories, respectively. Changes in protein and calorie intakes in other strata will influence nutrition only if the changes result in deficiencies.

The average daily per capita intake of calories and protein for the sample as a whole was estimated to be 119% and 112% of requirements (table 4). Hence, no additional food would be needed to fulfill calorie and protein requirements if available food were distributed according to needs. This situation clearly points out the inadequacy of average data as a measure of nutritional status.

Table 5 shows the proportion of the supply increases obtained by deficient strata. As might be expected, a relatively small proportion of an increase in the supply of meats, eggs, milk, and certain grain legumes would be consumed by protein and calorie deficient groups. Hence, efforts to improve human nutrition through the expansion of the supply of these commodities would entail a considerable "waste" of nutrients. For example, 71% of the protein generated from an increase in beef

Table 5. Percent of Supply Expansion Expected to be Consumed by Calorie and Protein Deficient Strata

production would be wasted in a nutritional sense, while this would be true only for 58% of the protein from additional bean production.

The direct, indirect, and net effects on per capita calorie and protein intakes for deficient and nondeficient strata are shown in tables 6 and 7. To save space, only the estimates obtained for supply elasticity equal to 0 are shown. It should be noted that the net effect decreases for increasing supply elasticity. (Only a few commodities are shown; estimates for all the commodities may be obtained from the authors.)

The net effect is determined by the increase in consumption of the food for which the supply curve was shifted (i)—the direct effect—and the resulting adjustment in the consumption of all other foods (j)—the indirect effect. Hence, the net effect is estimated as the sum of the changes in consumption of all foods, brought about by a shift in the supply curve of one of these foods.

The net impact on per capita calorie intakes among calorie deficient strata is relatively high for basic staples such as cassava, maize, and rice, while beef, maize, and rice provide the largest impact on per capita protein intake among deficient groups. The nutritional waste associated with an increase in the supply of meats, milk, lentils, peas, tomatoes, and fruits is illustrated by the greater increase in per capita calorie and protein intakes among nondeficient groups. However, in spite of the waste, a certain percentage increase in beef supply provides a larger net impact on protein intake among protein deficient groups than an equal percentage increase of any other single food. The large negative indirect effects within deficient strata associated with increases in the supply of certain foods is a result of high direct price elasticities for these foods (absolute value in excess of one), severe budget constraints, and relative nutrient contents. When the supply of one of these foods increases, total consumer outlay for the food increases. Since a large portion of the household budget is already committed to food, outlays for other foods tend to decrease as reflected by cross elasticities, the net result being a smaller nutritional impact than that

Table 7. Change in Protein Intakes (G./Capita) Caused by a 10% Increase in the Supply of Any One of the Foods for $Es = 0$

Foods for Which Supply Is Increased	Deficient Strata			Nondeficient Strata		
	Direct	Indirect	Net	Direct	Indirect	Net
Beef	1.41	−0.15	1.26	1.98	0.07	2.05
Milk	0.42	−0.08	0.34	0.59	0.04	0.63

Cassava	0.09	0.05	0.14	0.04	−0.35	−0.31
Vegetables	0.10	−0.03	0.07	0.08	0.02	0.10

reflected by the increase in the supply of a certain food. Increasing the supply of certain foods may actually reduce total protein and calorie intakes among deficient groups because the absolute value of the negative indirect effect exceeds the direct effect. Increasing the supply of peas and tomatoes was found to reduce total calorie intake by deficient groups, while protein intakes would decrease by increasing supplies of oils and fats.

The actual reduction in calorie and protein deficiencies that can be expected from supply expansions of the magnitude considered here are small (table 8). If supply elasticities are equal to 0, a 10% increase in the production of maize or rice would reduce calorie deficiencies by 16%–18% and protein deficiencies by 8%–9%. A similar percentage increase in beef production would reduce protein deficiencies in strata I and II by 6% and 15%, respectively. As supply elasticity increases, the nutritional impact of a shift in the supply curve diminishes. If supply elasticities are equal to one, a 10% increase in the production of maize or rice would reduce calorie deficiencies by 5%–6% and protein deficiencies by 2%–4%.

In view of the fact that the quality of protein consumed plays a major role in determining the nutritional level, it was attempted to analyze the impact on the intake of the three essential amino acids, lysine, methionine, and trytophan. It was found, however, that the diets contained more of these amino acids than required at all income levels. Hence, for the family as a unit, it appears that quantity of protein is more important than quality for the population studied. However, an analysis of the intrafamily food distribution is required to determine the relative scarcity of quantity versus quality of protein among the most vulnerable groups: infants, young children, and pregnant women.

Utility for Establishing Commodity Priorities

The empirical findings of this study clearly point out that relative increase in total nutrient supply is a poor indicator of relative nutritional impact. The nutritional waste defined earlier differs considerably among commodities. Furthermore, the adjustment in the consumption of foods, other than the one for which supply is increased, is of considerable importance in determining the final nutritional implications.

In addition to the relative nutritional impact, as estimated here, the relative cost of research, policy, and related activities needed to facilitate the supply expansion must be estimated in order to establish commodity priorities with highest nutritional impact per unit of resource invested in such activities. Changes in production costs need not be considered here since they will be reflected in the supply elasticity, which in turn participates in determining the new market equilibrium.[6]

While the research and policy costs are to be estimated for each individual project, three alternative cost assumptions are made here to illustrate how the information presented may complement estimated research and policy costs in establishing commodity priorities. The three assumptions are that (*a*) an equal percentage increase in the supply of any one of the foods considered can be obtained at equal costs, (*b*) an equal increase in the supply of any one of the foods measured in terms of quantity (weights) of the food can be obtained at equal costs, and (*c*) a given amount of calories and protein, respectively, can be supplied from any one of the foods at the same

[6] Since this analysis considers only one goal, improved human nutrition, the implications for other possible goals such as the distribution of benefits between consumer and producer sectors and among production factors are not discussed here. For a discussion of these relationships, see Ramalho de Castro and Schuh.

Table 9. Suggested Commodity Priorities if Improved Calorie Nutrition Is the Goal

4	Cassava	Plantain	Rice	Beans	Plantain	Plantain
5	Plantain	Oilseed	Wheat	Wheat	Sugarcane	Beans

costs. The commodity priorities for each of the assumptions are shown in tables 9 and 10, for supply elasticities equal to 0 and 1. The priorities are established on the basis of relative reduction in calorie and protein deficiencies expected from the increase of the supply of any one of the commodities, where the supply increases correspond with the above three alternative assumptions. The underlying numerical estimates are shown for assumption (*a*) only (table 8).

Depending on the relative costs of research and policy measures needed to facilitate supply expansions among the various commodities, this analysis shows that rice, oilseed, cassava, and potatoes would provide the most effective means for improving calorie nutrition in the population studied and beef, beans, and maize would be most effective in meeting protein nutrition goals. Maize appears among the five priority commodities for all costs assumptions and supply elasticities, whether calorie or protein nutrition is the goal. Hence, under any of the cost assumptions considered here, it appears that high research and policy priority should be placed on that commodity if both calorie and protein nutrition are goals.

As the supply elasticity increases, expanding supplies of commodities with high absolute direct price elasticities such as beef and to a lesser extent beans become more important in fulfilling nutritional goals, while expanding supplies of commodities with low absolute price elasticities such as cassava become less important. This phenomenon is explained by the sharper price drop of commodities with high absolute price elasticity of demand and the resulting larger quantity response to the magnitude of the supply elasticity. However, the magnitude of the supply elasticity does not greatly influence relative commodity priorities.

Final Comments

The present analysis has attempted to demonstrate how economic analysis may provide guidelines for establishing commodity priorities in agricultural research and production-oriented public policy if improved human nutrition for the urban population is a goal.[7] The analysis assumes that the expanded food supply resulting from the research and policy activities is in excess of increases in food demands at current prices caused by factors such as increased consumer incomes and population, i.e., such demand increases are expected to be fulfilled in the absence of the proposed activities. If this is not the case and research and public policy is needed partly to meet

[7] Although not treated in this article, implications for human nutrition among the rural population may be equally or more important and offers, in our opinion, another highly disregarded but potentially rewarding area of economic study.

Table 10. Suggested Commodity Priorities if Improved Protein Nutrition Is the Goal

Order of Priority	Cost Assumption (*a*) $E_{si} = 0$	Cost Assumption (*a*) $E_{si} = 1$	Cost Assumption (*b*) $E_{si} = 0$	Cost Assumption (*b*) $E_{si} = 1$	Cost Assumption (*c*) $E_{si} = 0$	Cost Assumption (*c*) $E_{si} = 1$

4	Beans	Beans	Rice	Maize	Beans	Beans
5	Potatoes	Potatoes	Beef	Rice	Eggs	Eggs

demand increases at current prices, the present analysis would apply only to the supply expansion in excess of demand expansions at current prices.

It appears from the empirical analysis that the problem of malnutrition in the population studies is basically one of absolute poverty among certain groups. While new technology resulting in shifts in the supply curve and reduced prices are important to improve human nutrition, the full potential of such technology for improving human nutrition is reached only if accompanied by rapid increases in incomes among low income consumers. Available quantities of food were estimated to be sufficient to provide an adequate calorie and protein diet for all sample members. Yet, even when using average family data, considerable deficiencies were identified. It is likely that much more severe deficiencies would have been detected if data were obtained on intrafamily food distribution.

Even though malnutrition in many cases might be reduced or eliminated through a more even distribution of incomes and/or food, such redistribution is likely to be slow at best and it appears that improved information on nutritional implications of alternative agricultural production research and policy measures may contribute to improved human nutrition even in the absence of such redistribution.

The authors of this article do not suggest that improved nutrition be the sole goal of agricultural research. We do suggest, however, that there exists an urgent need for developing and empirical testing of methodology useful to assist in establishing commodity priorities in research and public policy where improved human nutrition is one of the final goals. It is hoped that this analysis provides a modest contribution to such efforts.

Peasants' Response to Modernization Projects in *Minifundia* Economies

Carlos A. Benito

Different factors are mentioned in explaining peasants' adoption of modern technologies. A model of the peasant household is developed integrating most of these factors, condensed into a stochastic linear programming framework, and applied to the Puebla area in Mexico. Observed low adoption rates and peasants' participation in modernization projects are explained by opportunity costs of time and uncertainty. The view that labor-using technologies per se will rapidly increase agricultural production is challenged. The generation of less risky technologies and more emphasis on organizational-communication aspects are also necessary. Further rural development will require intermediate technologies and organizations.

Key words: adoption, allocation of human time, information, organizational activities, safety-first rule.

An important question in appraising rural development modernization projects is: what are the factors explaining the rate of adoption of the recommended technical practices? Researchers from various fields of the social sciences have been observing and explaining patterns of adoption among peasants under different socioeconomic structures. Principal explanations have related to the fundamental behavioral rule of peasant families, e.g., motivation in general (Chayanov, Lipton, Schultz) and behavior under uncertainty (Moscardi, O'Mara, Roumasset); the admissible set of opportunities for the peasant family, e.g., within the household (Hymer and Resnick, Sen) or in relation to village or community (Cancian); and the dynamics of communication and social group formation (Rogers, Diaz and Felstenhausen).

The proposition of this paper is that most of these explanatory factors can be consistently integrated into a choice model. Empirical research about the Puebla area in Mexico demonstrates that this model can represent the anthropological content of peasant household units acting within *minifundia* types of socioeconomic structures, i.e., part-time farming within small holdings combined with labor market activities.[1] The process of community organization used by modernization projects like the Puebla Project in Mexico (e.g., the formation of credit groups) is also represented by such a model.

The Puebla Project is a modernization project devised as a strategy for rapidly increasing yields of maize among small holders (CIMMYT). Operationally, it is a package of technological recommendations and organizational practices reducible to the following components: technical information about the optimal use of fertilizer to produce maize, a time schedule for fertilizer application, guidance concerning plant density, a suggested procedure for facilitating access to the fertilizer market, and a procedure for obtaining access to credit. The first three items comprise a technological package geared to increase corn yields, while the last two integrate the organizational element. In the Puebla Project, fertilizer and credit are tied sales because credit is given to participants for the specific purpose of buying fertilizers.

After seven years of experience with the Puebla Project, one of the best-controlled experiments in modernization, the rates of adoption of recommended technologies still are relatively low (table 1). This is a puzzle for

policymakers and social scientists who, assuming the existence of "surplus labor," investigate the diffusion of labor-intensive practices within subsistence economies. A solution to this puzzle is all the more necessary in the face of the high priority that various international agencies (e.g., the International Bank for Reconstruction and Development, international research centers, etc.) and national agencies are giving today to modernization projects as a frontal attack on the world food problem.

A methodological proposition of this paper is that reduced-form models and one-modal explanations of adoption are insufficient to investigate that puzzle. What is necessary is a structural form representation of the peasant household economy that could incorporate the various factors that explain adoption.

One of the major results of this study is to show that modern technologies will be adopted by peasants at a low rate when the opportunity cost of their time in the labor market is relatively high. This will be true when the recommended technology is labor using and when access to modern input and credit markets is through a community organization process that is also time consuming. Although the model shows that peasants with larger holdings will adopt at a faster rate, an explanation is also provided for the paradox observed by several researchers that some groups of peasants with smaller holdings evidence the highest rates of adoption (Cancian, Peters). The risky nature of agricultural production and labor earnings in a subsistence economy is also represented. When the behavior of peasants under uncertainty and imperfect information is introduced into the model, an additional explanation for different patterns of adoption among peasants is found.

The remainder of this paper presents a description of the model developed in this study and its application to the Puebla Project. First, the major components of the structural form of a model of the peasant household economy are developed. Next, the model is condensed into a linear programming version in which risk, uncertainty, and information are incorporated by means of a safety-first rule. Then, by means of plausible assumptions and simplifications, an otherwise dynamic and nonlinear model is transformed into a simpler linear model so that the linear programming algorithm may be used to obtain solutions. Finally, this model is applied to the case of the Puebla Project in Mexico with results that explain the relatively low diffusion rates observed in the Puebla area during the first seven years of the modernization project. (A more expanded version of this study has been developed in Benito 1974).

A Model of the Peasant's Household

The Peasant's Economy within the Traditional Village

The total available time of the peasant household, s, is allocated between agricultural activities, s_a, nonagricultural working activities, s_w, and other household activities, s_h:

$$(1)\ s - s_a(t) - s_w(t) - s_h \geq 0,\ t_0 \leq t \leq t_1.$$

Agricultural time, s_a, is allocated in proportion, π_a, to farming, in proportion, π_k, to learning and gathering information about modern agricultural practices, and in proportion, π_o, to organizational activities:

$$(2)\ \pi_a(t) + \pi_k(t) + \pi_o(t) = 1,\ t_0 \leq t \leq t_1.$$

The last two types of activities are open to peasants through modernization projects. Nonagricultural working activities include self-employed activities (crafts, trade, etc.) and working in the labor market. From here on, the paper will concentrate on labor market activities alone.

The set of feasible agronomic practices is represented by the following stochastic production function:

$$(3)\ Y(t) = G_a\,[s_a(t)\cdot\pi_a(t),\ x_a(t),\ C_a(t),\ C_k(t),\mu\,(t)].$$

The concave function, $G_a(\cdot)$, expresses expected agricultural production, Y, as a positive function of labor time, $s_a\pi_a$; agroinputs, x_a; services from physical capital, C_a; services from human capital, C_k; and a stochastic factor μ (e.g., weather). The introduction of services from human capital (i.e., knowledge and information of agricultural practices) transforms the technology into an endogenous variable. Low levels of human capital indicate knowledge (in some abstract units) of only "traditional" practices, while high levels indicate knowledge of "modern" practices.

The total labor time allocable to farming activities is constrained by the availability of other resources, mainly land size, C_a, and by the over-all nature of the technology (in this case, a labor-intensive technology).

The agricultural production Y can either be sold in the proportion θ_m at price p_m or consumed by the peasant family in the proportion θ_c:

(4) $Z_a(t) \leq Y(t)\theta_m(t)p_m(t),\ t_0 \leq t \leq t_1,$

and

(5) $\theta_c(t) = 1 - \theta_m(t),\ t_0 \leq t \leq t_1,$

where Z_a represents sales of agricultural products. The degree of commercialization, θ_m, is determined at each point in time according to the motivation and structure of the peasant family as well as market conditions.

Earnings generated in the labor market, Z_w, are represented by

(6) $Z_w(t) = s_w(t) \cdot g_w[C_w(t)],\ t_0 \leq t \leq t_1,$

where the supply wage rate $g_w(\cdot)$, is an endogenous variable in the long run, since workers can increase it by investing in on-the-job experience, C_w. Occupational opportunities outside the farm are subject to

(7) $s_w(t) \leq g_e[C_w(t)],\ t_0 \leq t \leq t_1,$

indicating that the peasant's employment opportunities, $g_e(\cdot)$, in the labor market are limited, although in the long run they can be enhanced through investment in on-the-job experience.

Development through Modernization Projects

The economic performance of the peasant household depends both on the wealth of the individual household and its village social power. The peasant household wealth at each time t is integrated by the accumulated physical capital, C_a, and the embodied human capitals, C_k and C_w. The village social power, C_o, determines the accessibility of the peasantry to modern input, output, and credit markets.

Modernization projects promote the adoption by peasants of new practices and modern inputs through new knowledge and information and organizational help. Acquisition of new knowledge and information for a peasant represents an investment in human capital, $\partial C_k/\partial t$. Organizational help facilitates the formation of credit groups (*grupos solidarios*) that increase the social power of the peasantry, $\partial C_0/\partial t$. The *grupos solidarios* enhance the financial liability of this social group and provide an organizational structure which facilitates its accessibility to the modern inputs and credit markets:

(8) $x_a(t) \leq G_x[C_0(t)],\ t_0 \leq t \leq t_1,$

and

(9) $B(t) \leq G_b[C_0(t)],\ t_0 \leq t \leq t_1,$

where $G_x(\cdot)$ and $G_b(\cdot)$ are marketing and financing functions, respectively, and B is credit received from banks.

The major investment cost involved in learning and becoming organized is the opportunity cost of the human time of each peasant household. However, a more detailed study of the adoption problem will require a specification of the social process of group formation (Benito).

Motivations of the Peasant Household

An empirical premise of this study is that the peasant household allocates its human time and the market products so as to maximize the discounted utility, $F(\cdot)$, of expected consumption, Z_c, of purchased goods and home-grown food:

(10) $\max W_0 = \int_{t_0}^{t_1} F[Z_c(t)] \exp\left[-\tau(t - t_0)\right] dt,$

subject to the survival constraint (Lipton, Moscardi)

(11) $P[Z_c(t) \geq Z^*_c] \geq (1 - \alpha),\ t_0 \leq t \leq t_1,$

where τ is the subjective rate of time preference, $P[\cdot]$ indicates probability, Z^*_c is a minimum subsistence level that is biologically and culturally determined, and α is the subjective probability of disaster.

For the special case when $\alpha = 0$ and the subsistence constraint is effective (i.e., $Z_c = Z^*_c$), the conditions of "pure subsistence behavior" are determined. This can be interpreted as in the case of a peasant economy described by Chayanov and some anthropologists (Wolf). In this case of pure subsistence behavior, besides the utility $F(\cdot)$ that a peasant assigns to a given level of consumption, he will also attach to it the utility of survival.[2] In this situation there is an incentive for faster adoption of new technologies and, hence, an answer to the puzzle investigated by Cancian and observed in the Puebla area by Peters—that very small farmers can be faster adopters than medium-size farmers.

A Linear Stochastic Model of Peasant Households

A Linear Programming (LP) Model

The basic features of the above model can be condensed into a linear model. It is assumed that the allocation of time between working activities, $s_a + s_w$, and other household activities, s_h, has already been determined, and the model concentrates on the investigation of the time allocation between working activities. In addition, it is assumed that the utility function is linear in expected consumption and that expected consumption is a monotonically increasing function of full expected income H. This is a plausible assumption with regard to peasants with earnings close to subsistence levels. Furthermore, the peasant's household behavior under uncertainty and under different degrees of information is represented by a safety-first rule (Telster):

$$(12)\quad \max H = F(\cdot) + q_{w1}\Delta C_{w1}, \quad \text{subject to } P[F(\cdot) \geq Z^*_c] \geq (1 - \alpha),$$

where q_{w1} is the demand price of one unit of investment in on-the-job experience and ΔC_{w1} is this investment in human capital.

The demand price of human capital is an exogenous variable in this LP model. This specification transforms a multistage control problem into a simpler one-stage programming case. The certainty equivalence of the above formulation is

$$(13)\quad \max H, \text{ subject to } P[F(\cdot) - \eta_\alpha \sigma^*_f] \geq Z_c,$$

where η_α is a cumulative distribution function of total income and σ^*_f is perceived standard deviation of total income. The value of η_α is estimated from a standard normal table.

The empirical model represents the economy of an "average" peasant household in Puebla, Mexico, which produces only maize. A complete LP tableau is formulated in table 2.

Maize production can be generated by means of two activities: a traditional agronomic practice labeled with the subindex t and a modern practice recommended by the Puebla Project identified by the subindex m. There also exist two major job opportunities depending on the previous level of investment in human capital: job 1, a permanent type of job, subject to a minimum demand constraint, $g_{min}{}^1$ (row 9), and job 2, a temporary job subject to a maximum demand constraint, $g_{max}{}^2$ (row 10). Job 1 pays a higher wage rate than job 2 and, in addition, generates on-the-job experience that is measured by the time worked in job 1, i.e., $\Delta C_{w1} = s_{w1}$.[3]

The value B of constraint (11) measures the level of the peasant's savings that can be used to buy fertilizer. The funds that he can borrow from banks or from other credit institutions depend on the time that he allocates to organizational activities, s_o (column 11). The level of s^*_o, determined by the optimal solution of the LP model, will be a proxy for the peasant's "participation" in the Puebla Project.

Farm income is the only stochastic variable considered in this model. Based on a priori information, it is assumed that yields from traditional farming and modern farming are closely related, since both are subject to the same ecological conditions. For analytical simplicity, their correlation coefficient is assumed to be positive and one. These assumptions, which are plausible for the case of the Puebla area, transform a nonlinear programming model into the much simpler case of a linear programming model.[4]

[2] When the constraint is effective, the Lagrangian multiplier representing the marginal utility of survival becomes positive. Therefore, in the behavioral rule (first-order condition) of the peasant's demand for agronomic inputs x_e, the benefits of production are also weighed by this marginal utility of survival (Benito).

[3] One limitation of introducing a minimum constraint, $g_{min}{}^1$, is that the peasant may be forced to seek permanent employment under all circumstances. One wants this lower bound constraint to operate only in the event that the permanent job is considered and zero otherwise. This will require an integer LP algorithm to solve. However, this theoretical limitation did not affect the empirical study for two reasons: it was a binding constraint and the peasant was considered to have only one job alternative (permanent or temporary).

[4] If the assumption that a correlation coefficient equals 1 was not met, the specification used in the LP model will give an upward bias in the estimated standard deviation.

Table 2. Tableau for the Linearized Peasant Family Model

Constraints			Farming Activities							Labor Market Activities			Project Participation	Perceived Deviations

12. Safety-first rule	Z^*_r	≤			p_a	$-p_n$	$-p_{ph}$	$-p_p$	$-p_f$	w_1		w_2		$-\eta\sigma^*_{at}$	$-\eta\sigma^*_{am}$
13. Combination constraint, σ_t^*	0	=	1											-1	
14. Combination constraint, σ_m^*	0	=		1											-1

Empirical studies indicate that the observed distributions of corn yields in the Puebla area are normal (CIMMYT). It is assumed that the peasant knows from experience both the form of the distribution, i.e., normality, and its two first moments, the mean and the standard deviation.

Finally, the model distinguishes between the perceived (or subjective) distribution of probabilities and the observed (or objective) distribution of probabilities for each activity, i.e.,

$$\sigma^* = \beta\sigma, \tag{14}$$

where σ is the (objective) standard deviation "observed" by researchers, σ^* is the (subjective) standard deviation "perceived" by the peasant, and β is the degree of information of the peasant, which can be $\beta = 1$ when he has complete information or $\beta > 1$ when he has incomplete information.

In the empirical analysis of the study, it is assumed that the perception of the standard deviation of yields from traditional farming coincides with the observed. The justification for this assumption is that through long experience a peasant has gathered sufficient information to know what is the actual standard deviation. However, based on previous empirical studies (Villa Issa) and personal observations, it is assumed that the perceived standard deviation of maize yields from modern technology is higher than the one observed in the agronomic experiments conducted by the Puebla Project team.

Solution of the Linearized Model

Table 3 presents the empirical information for the solution of the model. Once an optimal solution is obtained for the LP model of the average peasant family, the quantitative changes in adoption rates are investigated for two major cases, first, when the physical and human capital endowment of the family is different from that of the average case, e.g., different size of landholdings and/or different job opportunities, and, second, when for a given family with permanent job opportunities the displacement of the equilibrium is studied when the wage rate changes. This is valuable information for designers and managers of modernization projects.

Case 0 of table 4 presents the results of the optimal solution of the LP model. The average peasant family will adopt the modern technology but only partially; 40% of the land will be cultivated in accordance with the Puebla Project recommendations, while the remainder remains under traditional methods. Subsistence income is a bounding constraint, and the peasant will opt for (technical) diversification. An alternative interpretation is that the peasant will utilize a technique that represents a

combination of the traditional and modern practices (table 5).

As the peasant's savings are not sufficient to cover the recommended fertilizer expenditures, he joins a solidarity group allocating a full five days to organizational activities.

Case 1 of table 4 shows that, if the peasant's perception of risk coincides with the observed risk of modern utilization practices, e.g., $\sigma^*_{am} = \sigma_{am} = 760$, his adoption rate will be higher than in case 0. A different pattern of allocation of resources is generated because the safety-first rule no longer is a bounding constraint. The peasant now perceives modern practices as a more profitable activity, and he allocates more time to organizing activities in order to obtain more credit. The difference in net income between cases 1 and 0, i.e., 1,325 pesos, is the household's value of agronomic information (Gould).

Case 2 of table 4 shows that, if the peasant possesses 3.5 hectares of land rather than 2.5 hectares but all other conditions presented for case 0 are maintained, the rate of adoption of modern technology will increase. But still subsistence income is binding; 86% of the land is cultivated under modern practices and the remaining 14% with traditional practices. Under these circumstances, there will be no unemployment. Also, more time will be allocated to farming resulting from the increased size of the holding, the use of modern labor-intensive technology, and a considerable amount of time devoted to organizational activities.

Case 3 of table 4 presents the case of a peasant household whose members have access to permanent jobs. In this case the family's unemployment rate drops to zero. The subsistence constraint is not binding, and the household cultivates all of its land with modern technology and participates in organizational activities 3% of the time in order to obtain credit. The allocation of time to and the output from agricultural activities are the same as for case 1.

The supply of labor response to wage rate changes was studied by means of sensitivity analysis. Variations of the wage rate within the range of 20 pesos and 36.50 pesos will not affect the quantity of labor supplied to job 1. But since the observed average wage rate of permanent jobs is about 36 pesos, peasants with slightly better job opportunities (i.e., with wage rates equal to or higher than 36.50 pesos) will have fewer incentives to work on the farm and, *ceteris paribus*, to participate in the modernization project. This result challenges the effectiveness of labor-using technologies per se.

Conclusions

Differences among peasants in the endowment of human capital, physical capital, and organizational power determine the differences in opportunity cost of human time, transaction costs, and behavior in the face of risky events. The particular combination of these differences determines the observed distribution of adoption rates among peasant households.

The structural condition of the peasant economy studied in this paper challenges the simplest view that labor-intensive technologies per se will rapidly increase agricultural production and improve the peasants' welfare. If the aim of a rural development policy is to increase agricultural production in the *minifundista* sector, the following steps are necessary. At the level of agronomic research, the generation of less risky technologies is required, e.g., adaptability of the new high yielding varieties to differences in environmental conditions, and development of improved varieties and practices for crop systems. At the level of design and implementation of modernization projects, the organizational component should have as much importance as the information (extension) component. The Puebla Project is a good example of the complementarity between organization and communication in diffusion processes. At the adoption level an adaptive strategy shall be offered. For example, one might begin with a package of land-saving and labor-using technologies, such as the green revolution, so as to generate an accumulation process within the household, and then introduce more capital-using technologies. When doing so, two complementary approaches can be followed: to promote the development and adoption of "intermediate technologies" that are not labor displacing and can be produced within the rural sector and to continue the process of community organizing by developing "intermediate organizations"—as, for example, in a few cases of the Puebla Project in which solidarity groups bought tractors that were then rented to individual households.

Economists can provide valuable assistance in the design and evaluation of these types of programs if their research is grounded on a model of political economy that takes into account the overall opportunity set of peasant households within each specific socioeconomic structure and a structural form model of the allocation of human time at the household level. This simple application of economics promises to be a necessary substitute for reduced-form representations and one-modal explanations of the adoption problem.

Further theoretical and empirical research will require an expansion of the model to study the complexities of crop production systems (e.g., corn-bean combination) including the seasonal and intrafamilial allocation of human time (women-men and adults-children). The development of a multistage model to investigate the changes over time of peasants' perception of risk, β, due to learning experiences as well as the changes in the subjective probability of disaster, α_1, as resource constraints change will also be required.

A Stochastic Policy Simulation of the World Coffee Economy

R. Edwards and A. Parikh

The paper analyzes the structure of the world coffee market and suggests policies that stabilize the export earnings of coffee-exporting countries. The major cyclical characteristics of the coffee economy may be explained by a simultaneous equation model, which considers the lagged response of supply to price. The most successful policies include the development of rapidly maturing trees and the imposition of a quota on exports, both of which are effective in modifying the long-run cycle. A buffer stock policy is shown to be effective in eliminating short-run fluctuations, given sufficient resources.

Key words: buffer stock, fluctuations, quota, stochastic simulation, variance of export earnings, variation in maturation lag.

The aim of the paper is to analyze the structure of the world coffee economy and to suggest policies to minimize the fluctuations in export earnings of the coffee-exporting countries. An econometric model is outlined, and its predictive performance over the sample period is examined.

The coffee economy is simulated up to the year 2000, and various properties of the basic model are analyzed. Although the estimated equations are all subject to stochastic error, the simulations are carried out in both stochastic and nonstochastic frameworks, the latter treating all equations as if they were completely deterministic. Following the simulations of the basic model, policy instruments such as a buffer stock and a quota scheme are introduced in an attempt to evaluate their success in dealing with the various fluctuations.

The Model

A brief outline of some of the major characteristics of the coffee economy may assist in the understanding of the model. For coffee, there is a tendency for a year of high production to be followed by one of low production. Rourke indicates that the coffee tree suffers from the strain of a heavy harvest in such a way that it cannot carry as much fruit in the following year (p. 202). However, within large geographical areas it is likely that the various local districts will have their high and low production years more or less independently of each other. Consequently, it is only when small geographical areas are considered that the two-year pattern is likely to be pronounced. Various other factors influencing the size of the crop, including climatic factors, are considered in Rourke. Random fluctuations in coffee production, though not as violent as for many other primary products, are nevertheless quite substantial and may to an extent be due to the deliberate stock-holding policies of Brazil.

The low price elasticity of demand, along with the lagged response of supply to price, causes the long-run coffee cycle; small shortages lead to large price increases, inducing large scale expansion. After a maturation lag of about five years, this results in excess supply, leading to price decreases. The duration of these cycles appears to be about twenty years. The last cycle began with the upswing of the late 1940s, giving way to a downswing lasting from the mid-1950s until 1972. There are indications that this cycle has come to an end and that a new upswing is beginning. This, however, seems to have been hindered by technological and institutional developments. The introduction of rapidly maturing arabica trees and the countercyclical policies of curtailing new plantings during price booms,

WEP_t	=	World Exportable Production (1,000 metric tons)
USS_t	=	Stocks in the United States (1,000 metric tons)
IUS_t	=	Imports into the United States (1,000 metric tons)
IE_t	=	European Imports (1,000 metric tons)
IRW_t	=	Imports into the Rest of the World (1,000 metric tons)
PW_t	=	World Price of Coffee (cents/lb. on New York Market)
S_t	=	World Stocks (1,000 metric tons)
WI_t	=	World Imports (1,000 metric tons)
D_t	=	Dummy for even years
PW_t^*	=	Expected Prices (approximated by the moving average $(PW_{t-3} + PW_{t-4} + PW_{t-5})/3$).
π	=	Stationary Price (regarded as the "normal" price by producers, see Parikh 1974).
τ	=	Gestation Lag between Planting and Harvesting
ΔPW_t	=	Change in World Price
ΔIRW_t	=	Change in Imports into the Rest of the World
ΔS_t	=	Change in World Stocks
SEE	=	Standard Error of Estimate

along with the promotion of rehabilitation schemes during depression periods, have gone some way toward stabilizing production to the desired level. Attempts have been made on an international level to restrict sales and maintain price levels, notably by "Cafe Mundial" and "Cafe Suaves Centrales." These attempts have had very little success, so little in fact that even while the schemes were in operation coffee exports were at near record levels.

It appears, then, that fluctuations (both short-term annual variations and long-run cycles) persist in the world coffee market that require both explanation and control. It is hoped that the model outlined below will go some way towards this end.

A full discussion of the basic model is given in Parikh (1974). Consequently, its detailed derivation is not presented here. The main variables are defined in table 1, and the model is presented in its estimated form.[1] The model contains a simultaneous equation block within which world imports and world price are jointly determined, which is estimated by full information maximum likelihood (FIML), the other equations being consistently estimated by ordinary least squares (OLS). The t-statistics are given in parentheses (in the case of the simultaneous block, the figures are asymptotic t-ratios).

$$(1)\quad WEP_t = \underset{(15.47)}{2823.51} + \underset{(6.15)}{0.25} \sum_{\theta=1-\tau}^{t-\tau} (PW_\theta^2 - \pi^2) - \underset{(3.56)}{1281070}(1/PW_{t-2}^2) - \underset{(4.66)}{575.98}D_t.$$

$$\tau = 5. \qquad R^2 = 0.858.$$
$$\pi^2 = 1758.54. \qquad DW = 2.23.$$

$$(2)\quad USS_t = \underset{(2.55)}{123.20} - \underset{(2.11)}{0.07}\, PW^*_t + \underset{(4.51)}{0.57}\, USS_{t-1}.$$
$$R^2 = 0.504. \quad h = 4.02.$$

The following four equations are estimated by FIML.

$$(3)\quad IUS_t = \underset{(14.78)}{1901.82} - \underset{(2.97)}{1.09}\, USS_t - \underset{(4.99)}{9.40}\, PW_t.$$
$$\text{SEE} = 4.39\%$$

$$(4)\quad IE_t = \underset{(6.75)}{128.46} + \underset{(58.26)}{0.98}\, IE_{t-1} - \underset{(2.82)}{1.35}\, PW_t.$$
$$\text{SEE} = 3.26\%$$

$$(5)\quad \Delta IRW_t = \underset{(2.79)}{8.54} - \underset{(1.20)}{0.66}\, \Delta PW_t.$$
$$\text{SEE} = 6.09\%$$

$$(6)\quad PW_t = \underset{(2.65)}{54.64} - \underset{(6.57)}{0.005}\, S_{t-1} - \underset{(4.39)}{0.01}(WEP_t - WI_t).$$
$$\text{SEE} = 13.45\%$$

$$(7)\quad WI_t \equiv IUS_t + IE_t + IRW_t.$$

[1] The models are at a highly aggregate level. There is one "world price" and a "world" exportable production. From a realistic point of view, it is obviously desirable to consider various sorts of coffee and their respective prices separately and to differentiate between geographical areas. This would, however, greatly increase the size and difficulties of the model, and data on all the necessary variables are not available. The data used in estimation cover the period 1950–72.

(8) $IRW_t \equiv IRW_{t-1} + \Delta IRW_t$.

(9) $\Delta S_t \equiv WEP_t - WI_t$.

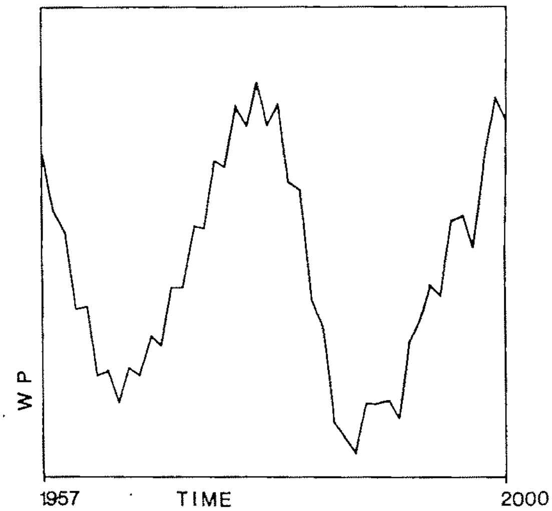
(10) $S_t \equiv S_{t-1} + \Delta S_t$.

An examination of the estimated relationships indicates that the explanatory variables account for 78% to 98% of the observed variation in the endogenous variables. The predictive performance over the sample period is satisfactory. There are, however, certain problems with the U.S. stocks equation, such as the obvious serial correlation (indicated by the Durbin h-statistic), but in view of the fact that it is purely a predictive relationship (servicing the U.S. imports equation) and the fact that data on these stocks are neither abundant nor very reliable, no correction procedure was carried out. Also, the coefficient of PW^*_t in this equation should a priori be positive but in fact turns out to be negative. A possible explanation lies in the quarterly data used in the estimation of this relationship. During periods of intensive roasting, existing inventory may be considerably drawn on. Although new purchases may be made to replenish the stocks, they need not be made in the same quarter. Similar results were obtained by Abaelu and Manderscheid.

Simulations of the Basic Model

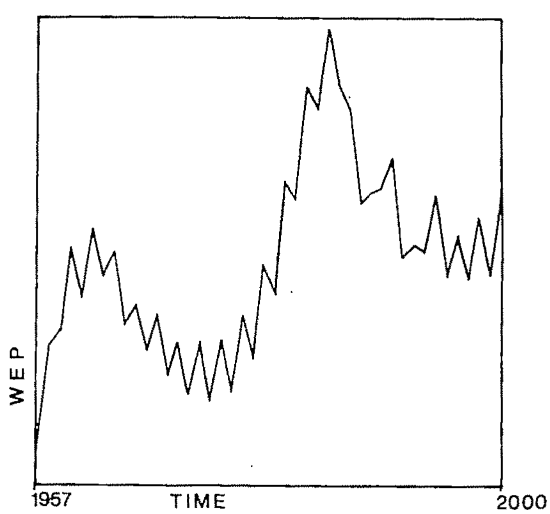
Several simulations of the model were carried out in order to determine its postsample period properties under varying conditions. The first simulation was nonstochastic, since some basis for comparison purposes was required. Following this, a normally distributed random element was introduced into each of the behavioral equations, with variances equal to the estimated sample variances of the error terms of the equations involved.[2] This enabled an assessment of the effect of the stochastic components on the cycles. The results of the stochastic simulations are based on the means and variances of the variables over twenty runs in order to eliminate spurious fluctuation.

Graphs of the important results are presented here. In these graphs, we are concerned with the shapes of the curves, which indicate the intensity of fluctuations. Consequently, although the scale is consistently preserved between graphs, the vertical axis does not indicate any numerical values.



Graph 1. World prices (nonstochastic simulation)

In the nonstochastic case, price displays a marked cycle of about twenty-years' duration (graph 1), the maximum of which is around sixty cents per pound, the minimum being about thirty cents per pound. There is little evidence of a trend. Exportable production also shows a cycle (graph 2) of about the same duration as that of the price variable, although out of phase with it by some seven to ten years. Here, the mean value displays an upward trend, as does the mean value of world imports. A similar cycle is exhibited by



Graph 2. World exportable production (nonstochastic simulation)

[2] This involves the assumption that the stochastic components have zero mean and finite variance over time and across equations. Also necessary is the assumption that error terms are normally and independently (of each other) distributed, with constant variance over time.

changes in stocks. An important feature is that excess supply (additions to stocks) is at a maximum when price is at a minimum, and vice versa. The mean value of excess supply is around zero, the generated series oscillating regularly between positive and negative, indicating that there is no tendency for stocks to diminish or accumulate over the simulation period.

A stochastic simulation of the model results in essentially the same pattern, except for minor residual fluctuations. There is also a tendency for the twenty-year cycles to be less violent than in the nonstochastic case. This particular result is consistent with the findings of Klein and Preston. There is a regular limit cycle of constant amplitude, the mean series of which is damped in a stochastic framework.[3]

Modifications of the Basic Model

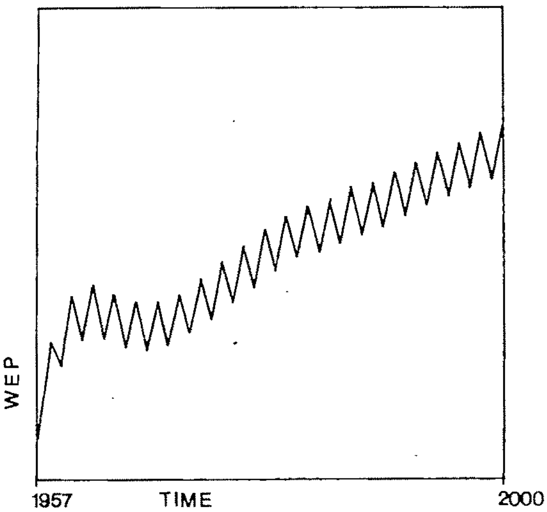
In order to obtain further information about the properties of the model and to determine the major causes of the long-run cycles, several modifications were made to the initial variant. First, the number of runs over which the means of the variables are calculated in the stochastic case was increased from twenty to one hundred in an attempt to determine the effect of sample size on the results. In fact, no noticeable difference is found. The cycles generated are of slightly smaller amplitude and display a tendency to be damped. The results, however, are almost identical to those of earlier stochastic simulations. Second, the period of simulation was extended to 250 years, to gain a better idea of the nature of the twenty-year cycle. The constant amplitude property was confirmed, indicating that the model belongs to a class of nonlinear models generating nondamped oscillations in a nonstochastic framework.

In order to test the hypothesis that one of the main causes of the long-run cycles is the response of world exportable production to price changes, it was decided to simulate the model with various changes in the price response coefficients in the exportable production equation (1), the estimated numerical values of which are 0.25 (long run) and −1281070 (short run) (see Parikh 1974). All combinations of these coefficients, plus or minus twice their respective estimated standard errors, were examined. With a high long-run and low short-run response, quite violent cycles resulted in all variables, displaying marked tendencies to be antidamped. With a strong short-run and weak long-run response, the pattern is reversed. Both price and exportable production display much gentler cycles than in the original case, with some tendency to be damped (although this conclusion is perhaps unjustified owing to the short simulation period). It would appear from this that if intervention, favorably affecting the response of production to price, were possible, then such a policy could break the cyclical behavior of the coffee economy, in principle.

A similar analysis was undertaken on the effect of changing the gestation period of coffee trees. As far as the model is concerned, this involves altering the value of τ in the exportable production equation (Parikh 1974). It is in fact known that the development of arabica trees that mature in three to five years has been a significant step towards the removal of the long-run cycle in arabica production. No such development, however, has taken place in the more fragmented Robusta production areas. Increased fertilizer usage and other technological advances have sometimes altered the natural foliage/bean cycle and could be responsible in part for the two-year price cycle. This is, however, far from conclusive (see Parikh 1971).

In the estimated model, a lag of five years between planting and first harvest was assumed. When this lag is increased to seven years, it is found that the long-run cycles become more pronounced, their duration increasing slightly. By reducing the gestation lag to two years, the model generates a heavily damped price cycle, rapidly converging to a more or less constant value of around forty-three cents per pound. A similar picture is presented by exportable production and changes in stocks. It is recognized that a two-year gestation period may be beyond the physiological limit with the current technology. However, the indication is that any reduction in the maturation lag will help to eradicate the long-run variations in production. Indeed, a lag of four years results in less violent cycles than the original case, although the tendency to be damped is not nearly so marked as in the two-year lag case (graph 3).

[3] If we were to predict the position of the system at a future time on the basis of the initial conditions, given a stochastic structure, we would not know which particular random realization to choose and would have to base the prediction on the expected value. It is the series of these expected values that we find to be damped.



Graph 3. World exportable production with two year maturation lag

Policy Simulations

Based on the original model, an examination was made of stabilization techniques designed to (*a*) modify the long-term cycle, and improve the trend in export earnings, and (*b*) reduce the amplitude of short-run fluctuations.[4] A priori, there is no single technique that could meet both objectives. However, the policy variables selected for consideration include intervention by a buffer agency (whereby direct attempts are made to stabilize prices), and a quota scheme (which attempts to impose artificial restrictions on the supply of coffee).

The welfare aspects of the stabilization of prices and earnings have been discussed by Massell. Possible criteria against which policies may be judged include their capacity to maximize expected earnings and to minimize fluctuations in those earnings.[5] Consequently, comparisons in this paper are made on the basis of the generated mean and variances of earnings over the simulation period.[6] This ideally involves the examination of the variation in earnings around a time trend, and in cases where this trend differs significantly between simulations, its effect was considered in the assessment.

Both of the policy variables require a "reference price" indicating some idea of the "desired" price level in each period. In practice, we use that range of prices determined by the reference price, plus and minus a constant. If the actual price lies within this range, no action is taken. Should, however, the actual price lie above the permissible ceiling or below the floor, there is a policy intervention, the magnitude of which is determined by the discrepancy between the actual and the ceiling or floor prices.

The reference prices used in the policy simulations are generated in two ways. The first involves taking a lagged moving average of the prices predicted by the model excluding the policy variable—rule A. This assumes that the authorities have access to the model and base decisions on it. The second method sets the reference price as a lagged moving average of the prices derived within the model including the policy variables and assumes that the authorities base decisions on past, observable price levels—rule B. In practice, after testing several alternatives, it was found that a two-year centered moving average of the most recent prices (both under rule A and rule B) was the most successful reference price from the point of view of the efficacy of both policies.[7]

Buffer Policy

In reality, the implementation of a buffer stock, which could adequately serve all major coffee-exporting countries, would involve complexities far beyond the scope of this study. In fact, such a policy is at present only within the financial and organizational range of a small number of arabica-producing nations and, as such, could only hope to affect a small section of the entire coffee economy. However, the incorporation of this sort of intervention into the present aggregate model will give some idea of its comparative success against other possible alternatives; perhaps not on an

[4] It must be assumed here that the structure of the model does not change with the introduction of the policy instruments. This may be particularly unrealistic with respect to the stocks equation, which may be significantly affected by the presence of a buffer agency. However, in the absence of the relevant data, it is not possible to reestimate the structure to take account of this.

[5] Earnings are defined as world imports multiplied by price, on the assumption that actual imports are equal to actual exports.

[6] The method most frequently used for the comparison of uncertain prospects has been this mean-variance approach. Rothschild and Stiglitz have attacked this approach and concluded that the results of such analysis may be spurious, only holding if the class of distribution is arbitrarily restricted. They suggest the use of a relative risk aversion parameter in a concave or convex welfare function. By evaluating the welfare gains in terms of expected earnings, an attitude of risk-neutrality is imposed, and in employing the variance minimization criterion, the assumption is implicitly made that the welfare function is such that an increase in variance (riskiness) is equivalent to a decrease in expected earnings.

[7] This is probably a consequence of the presence of the two-year product cycle.

institutional level but possibly on the grounds of logical feasibility.

A major problem in the simulation of this form of policy lies in the initialization procedure, involving decisions about the initial stock and fund of the agency and the specific form of intervention rule. Consequently, a large number of simulations were carried out for the purpose of determining the most successful initialization pattern.

It was initially decided to include some idea of a "desired level" of stocks into the intervention rule, in the hope that this would help stabilize prices, not only directly (through the "desired price" mechanism) but also through the effect of the level of stocks on prices. However, the stock term tended to dominate, and sometimes led to perverse results (e.g., when prices were too high, stocks were too low, and since the stock consideration was strong, the agency bought coffee to build up inventories, and the price was pushed up further). Consequently, this consideration was dropped, and the final form of the intervention rule was

$$BS_t = a(PR_t - PW_t), \tag{11}$$

where BS_t represents the change in the level of stocks held by the buffer agency in year t, and PR_t represents the ceiling or floor price. The size of the parameter a is not a real problem, since the process of adjustment is iterative, transactions continuing in any year t until the actual price converges on to a stable value. Consequently, the numerical value of a only affects the speed of adjustment in any one period. In fact, it was set equal to 14, since after trial and error this represented a reasonable compromise between excessive computer time and the possibility of nonconvergence.

The reference price range was initially set to

$$PR_t = \frac{(PW_{t-1} + 2PW_{t-2} + PW_{t-3})}{4} \pm 5 \text{ cents/lb.} \tag{12}$$

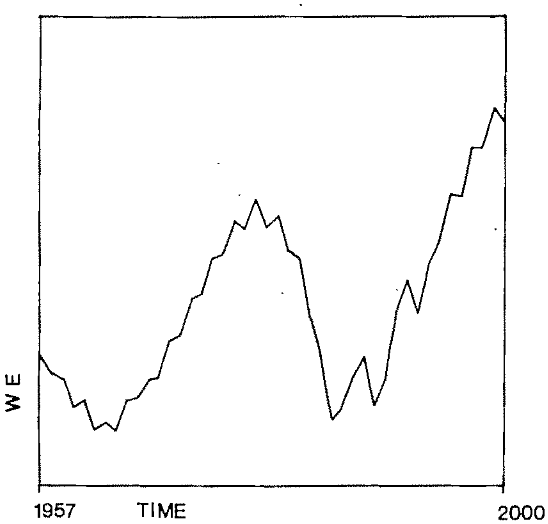
However, in an attempt to obtain an upward bias on the level of prices in order to improve earnings trends, it was decided to effectively narrow the permissible band in the downward direction, and the final form of the reference price range was Ceiling = Reference Price + 5 cents/lb. and Floor = Reference Price − 2.5 cents/lb.

The main problem in the initialization of the buffer stock (and indeed the problem that hindered its operation in later simulations) was the setting of the initial stock and fund of the agency. This was particularly crucial, since a constraint was built into the simulations, limiting the operation of the agency in accordance with its available resources. Thus, transactions involving the buffer agency could continue only so long as stocks or funds remained positive, where the buffer agency was required both to buy and sell at the current world price.

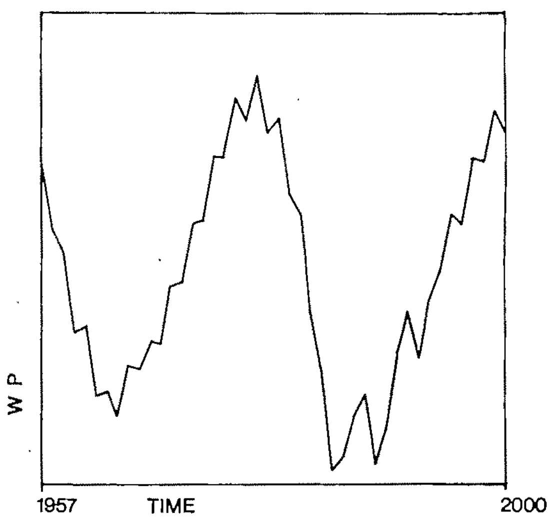
The first initial fund and stock figures considered were \$500,000 and 1,000 metric tons, respectively. In many ways, these are ridiculously low figures and indeed resulted in an almost completely ineffective agency. After a certain amount of trial and error, the final values were set to \$40 million of fund and 50,000 metric tons of stock. One of the main conclusions of this set of simulations was that to be really effective the buffer agency must operate on a very large scale. For cocoa, for instance, the Organization has accumulated funds of \$50 million and envisages a stock of about one-fifth of the entire world crop. The finance for this scale of operation has been a major cause of dispute in the International Coffee Agreement negotiations on this policy. Even with this higher level of resources, intervention by the simulated agency was often hampered by insufficient stock and finance.

This initialization procedure was, somewhat unrealistically, carried out exogenously (i.e., the fund and stock were assumed to be already available so that no initial purchases were required). Also, no storage capacity constraint was considered, although this would obviously limit the agency's actions to a very large degree. With this final set of initial conditions, there is an actual worsening of the cyclical behaviour of the economy under policy intervention. Under both rule A and rule B, the means of both prices and earnings fall, and there is an increase in their variances. There is evidence to suggest that the policy, especially under rule A, is successful in reducing short-run fluctuations (graph 4). This being the case, the increases in the variances can only be attributed to an actual aggravation by the policy of the long-run cycle.

Even when the policy is included in a stochastic simulation of the model, no improvement results. Although under rule A there is an increase in mean price from forty-two cents per pound to forty-seven cents per pound, its variance is almost doubled. Al-



Graph 4. **World earnings with buffer stock policy intervention (rule A)**



Graph 5. World prices with buffer stock policy intervention (rule A)

though the variance of earnings falls by 25%, there is a fall in its mean by about $17 million per year. There is also evidence to suggest that the twenty-year cycles have become antidamped (graph 5). The antidamped nature of the cycles is more pronounced under rule B, although short-run fluctuations are considerably reduced.[8] This is perhaps explicable in terms of the implicit difference equation describing price. Especially under rule B, where the reference price is determined by lagged values of the endogenous price variables, the roots of this equation may have been increased beyond unity by the inclusion of the policy and would account for the antidamped nature of the cycles.

The failure of the buffer agency to make any consistent reduction in the fluctuations in earnings may be explained in two ways. First, it involves an essentially short-term policy, which does not take long-run cycles into account in the determination of its reference prices or interventions. Second, the fluctuations in coffee export earnings may be caused primarily by the supply situation. Work done by the International Monetary Fund and the International Bank for Reconstruction and Development suggests that, if this is the case, then a buffer agency will have little success and a policy that attempts directly to stabilize supply will be of greater value. One such policy is the imposition of a quota on exports.

Quota Policy

Although the quota policy requires a similar reference price to the buffer policy, the initialization procedure is much simpler. First, an initial quota must be determined for each year. It was decided to set this equal to the trend value of world imports in an attempt to maintain a dynamic equilibrium between world supply and demand. Second, a mechanism must be developed by which adjustments to the initial quota may be made, according to prevailing price levels. The simplest such mechanism is

$$QA_t = QI_t + a(PR_t - PW_t),\ a < 0, \tag{13}$$

where QI_t is the initial quota, QA_t is the adjusted quota, and PR_t is the ceiling or floor of the reference price range (determined as in the case of the buffer stock policy). The value of a in this relationship was set to -24.[9]

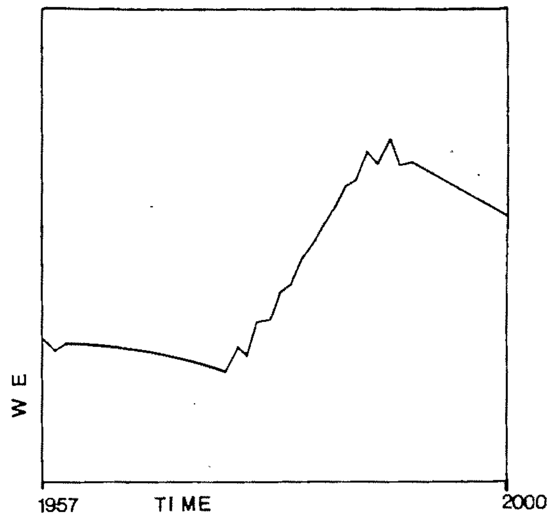
In order to take account of the fact that more than one quota adjustment is possible in any year, comparisons between the actual and

[8] All of the above simulations were carried out under the assumption that the buffer agency involves costless operation. In order to gain some idea of the costs involved, a separate simulation of the model was carried out. With a fixed cost of $2 million per annum, a variable cost of 5% of the value of stocks and a discount rate of 8%, the total discounted cost of the agency (ignoring initialization) was about $24 billion over the entire forty-four years of the simulation, indicating a very high cost relative to benefits. However, the particular figures considered may not reflect the situation facing an actual agency.

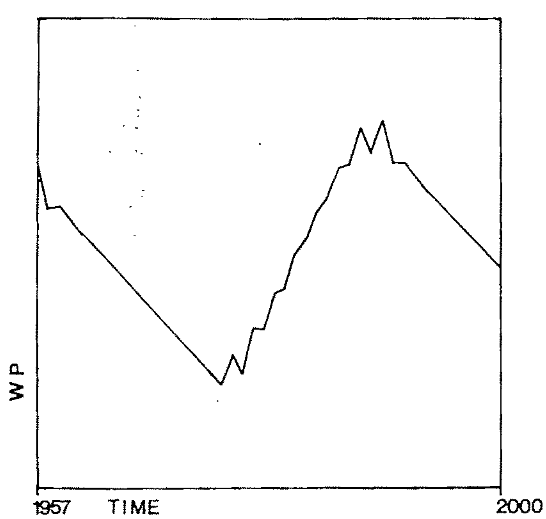
[9] In order to gain an idea of the response coefficient, the adjustment mechanism was estimated using data for the quota period (1964–72). Because of the low number of observations, the estimate of a cannot be taken as accurate, but it was felt that the general magnitude could be validly employed.

reference prices were made after every adjustment, and further modifications were made to the quota as necessary. This process continued until the price converged to a stable value, after which no further adjustments were made in that period. All simulations are carried out under the assumption that producers obey the quota restrictions on exports. This policy achieves a certain degree of success under rule A. In the nonstochastic framework, although mean earnings over the simulated period fall by about 2.5%, the variance is decreased by 20%. There is strong evidence to suggest that this fall in variance is almost entirely due to a reduction in the magnitude of short-run fluctuations, since there is no indication that the long-run cycle is significantly affected. A stochastic simulation results in a worse policy performance. Both the means of price and earnings fall, whereas their variances display increases. This appears to be caused by an increase in the amplitude of the long-run cycles, since the short-term fluctuations seem to have been eradicated. There is also a tendency for the cycles to be antidamped. The extremes on the first phase of the price cycle, for instance, are twenty-nine cents and fifty-seven cents per pound, whereas on the second phase they are twenty-three cents and fifty-nine cents per pound, respectively.

A nonstochastic simulation of the model under rule B, however, results in a much greater degree of success for the policy. Mean price increases by around 8% and mean earnings increase by 12%, while the variance of price falls by about 56%, that of earnings displaying a 21% decrease. This is to a large extent due to the total eradication of the short-run fluctuations over large ranges of the simulated period. It is also interesting that, although the amplitude of the long-run cycles does not appear to have been affected, their frequency is halved, so that each cycle has a duration of about forty years (graphs 6 and 7). These results are echoed in the stochastic simulation of this variant. The variances of price and earnings display 40% and 10% decreases respectively, while there are increases of 4% and 10% in their respective means. Again, the frequency of the long-run cycles is halved, while their amplitude falls slightly.



Graph 7. World earnings with quota policy intervention (rule B)



Graph 6. World prices with quota policy intervention (rule B)

Summary and Conclusions

The extent to which the simulated impact of the stabilization policies considered here reflects the actual capabilities of such instruments in the coffee economy obviously depends on the success of the model in capturing the underlying structure of the market. Many complexities have been ignored, and the simulations were carried out at a highly aggregate level. The somewhat unrealistic assumption is also made that the political and institutional factors necessary for the implementation of such policies are available. However, a crude comparison between various alternatives is possible within this framework, so that the

simulations have more than academic value. The main conclusions of the paper may be summarized as follows.

Coffee prices and production are characterized by strong long-term cycles, around which are found smaller short-run fluctuations. These may be explained to a large extent by a simultaneous-equations model, taking account of the lags in the responses of demand and supply to prices. Such a model was established to simulate the impact of alternative stabilization policies, the objectives of which were to improve the average level of earnings, to break the long-term cycle, and to reduce the amplitude of short-term fluctuations. The development of rapidly maturing varieties is the most natural and efficient way of breaking the long-term cycle. A reduction in the gestation lag from five to two years results in a complete cessation of the twenty-year pattern.

An international buffer stock policy can substantially reduce short-run fluctuations given the necessary resources, but may have an adverse effect on the long-term cycle. A quota policy is more successful, having few of the economic difficulties found in the buffer policy. However, owing to political considerations, it is probably much more difficult to enforce.

Impact of Farm Size on the Bidding Potential for Agricultural Land

Duane G. Harris and Richard F. Nehring

A theoretical model is constructed to determine the maximum bid price that would be made for an acre of land by a decisionmaker with a given set of characteristics, capabilities, and expectations. The variables included that have an impact on the maximum bid price are net income, income variability, wealth, degree of risk aversion, marginal income tax rate, rate of pure time preference, and expected rate of growth in land income and prices. A numerical illustration of the model, developed for cash-grain farmers in Iowa, demonstrates the relative importance of the variables in determining bid-price differentials among farm-size classes.

Key words: farm size, land ownership, land value.

The size structure of farms, the control of farming, and the future of the family farm are issues that are all related to the ownership and control of a unique rural resource—land. The future complexion of the U.S. countryside is intimately tied to the ability of different economic groups to gain and maintain control of the land base. Continuation of past trends in farm enlargement and off-farm migration would vest the control of the farming community in fewer and larger operating units.

Krause and Kyle have outlined many of the incentives for further potential increases in the incidence of large farming units: production and marketing economies, management expertise, tax incentives, nonfarm investment, specialization, and conglomeration (pp. 752–55). Armstrong acknowledges these incentives, but also cites potential limits or impediments that may temper the continued trend toward larger units: managerial talent availability, problems of coordination and supervision, capital availability, labor availability, and risk and uncertainty.

While previous studies have identified some important aspects of the farm size and control issues, the extant literature provides no overall theoretical framework within which to incorporate these key incentives and diseconomies. The purpose of this paper is to develop a theoretical approach that can be used to determine the relationship between land ownership and the various characteristics of existing farm size classes. It is assumed that the future ownership of land will be determined by the relative bidding potential of participants in the land market.

A theoretical model of maximum bid price is developed and discussed in the next two sections. Then an application of the model is made to cash-grain farms in Iowa. Finally, a summary and some conclusions of the study are offered.

Theoretical Model

The basis for the development of a theoretical model of bidding potential is provided by Pratt. In his formulation of a measure of the degree of risk aversion, he defines the bid price as the largest amount a decisionmaker would willingly pay to obtain a risky asset (p. 124). This bid price is given by the equation

$$(1) \qquad u(x) = E\{u(x + z - B)\},$$

where x represents the level of assets held by the decisionmaker; u, his utility function; E, the expected value operator; z, the risky asset;

Duane G. Harris is an assistant professor and Richard F. Nehring is a research assistant in the Department of Economics at Iowa State University.

Journal Paper No. J-8219 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa, Project No. 2066. The authors wish to thank Michael Boehlje for helpful discussions during the development of this paper. Appreciation is also extended to David L. Reinders for expert programming assistance. Finally, referees Kenneth R. Krause, Lloyd D. Teigen, Allen Smith, and an anonymous reviewer offered suggestions that markedly improved the manuscript.

and B, the bid price.[1] In this analysis, x will be interpreted as the level of net worth of the decisionmaker and z as a random variable denoting the value of an acre of land. The term B then represents the maximum price a decisionmaker would be willing to pay for that acre.

By using a Taylor expansion to expand u around x (Yamane, pp. 280–81), an approximation for the bid price can be derived from the quadratic equation

$$(2)\quad \tfrac{1}{2}\, u''(x)B^2 - [E(z)u''(x) + u'(x)]B + \tfrac{1}{2}\, \{\sigma_z^2 + [E(z)]^2\}\, u''(x) + E(z)u'(x) = 0,$$

where $u'(x)$ and $u''(x)$ are the first and second derivatives of the utility function, and $E(z)$ and σ_z^2 are, respectively, the expected value and variance of the value of an acre of land.

By utilizing Pratt's measure of local risk aversion (p. 125)

$$(3)\qquad r(x) = -\frac{u''(x)}{u'(x)},$$

equation (2) can be rewritten as

$$(4)\quad \tfrac{1}{2}\, r(x)B^2 - [r(x)E(z) - 1]B + \tfrac{1}{2}\, r(x)\{\sigma_z^2 + [E(z)]^2\} - E(z) = 0.$$

Solution of this quadratic equation gives B in terms of $r(x)$, $E(z)$, and σ_z^2:

$$(5)\quad B = E(z) - \frac{1}{r(x)} \pm \left\{\frac{1}{[r(x)]^2} - \sigma_z^2\right\}^{1/2} \quad \text{for } r(x) \neq 0,$$

and

$$B = E(z) \text{ for } r(x) = 0.$$

If, however, z is defined as the discounted value of future income from an acre of land and is derived from a standard perpetuity model incorporating a constant rate of growth (e.g., Van Horne, pp. 21–22), the value of an acre of land can be defined as

$$(6)\qquad z = \frac{y\,(1-t)}{(i-g)},$$

where y represents a random before-tax income stream, t is the marginal income tax rate of the decisionmaker, g is the expected rate of growth of after-tax income, and i is the decisionmaker's discount rate for pure time preference. Then $E(z)$ and σ_z^2, respectively, become

$$(7)\qquad E(z) = \frac{(1-t)}{(i-g)}E(y)$$

and

$$(8)\qquad \sigma_z^2 = \left[\frac{(1-t)}{(i-g)}\right]^2 \sigma_y^2.$$

Substituting equations (7) and (8) into equation (5) gives

$$(9)\quad B = \frac{(1-t)}{(i-g)}E(y) - \frac{1}{r(x)} \pm \left\{\frac{1}{[r(x)]^2} - \left[\frac{(1-t)}{(i-g)}\right]^2 \sigma_y^2\right\}^{1/2} \quad \text{for } r(x) \neq 0,$$

and

$$B = \frac{(1-t)}{(i-g)}E(y) \text{ for } r(x) = 0.$$

The maximum bid price B is defined in terms of the parameters of the utility function (through the measure of the degree of risk aversion, r(x)), which are the expected value and variance of income, $E(y)$ and σ_y^2; the expected rate of growth of income, g; the marginal tax rate of the decisionmaker, t; and the decisionmaker's rate of pure time preference, i. Specification of the values of these parameters and variables allows the calculation of the bid price for any potential purchaser of farmland.

Decisionmaker Characteristics and the Maximum Bid Price

The values of the parameters and variables in the bid-price equation (9) are related to the characteristics, capabilities, and expectations of the decisionmaker. An evaluation of the influence of these parameters and variables on the maximum bid price for an acre of land can be carried out by taking the partial derivatives of B with respect to $E(y)$, σ_y^2, $r(x)$, x, t, i, and g.[2] Thus,

$$(10)\qquad \frac{\partial B}{\partial E(y)} = \frac{(1-t)}{(i-g)} > 0,$$

and

$$(11)\qquad \frac{\partial B}{\partial \sigma_y^2} = -\frac{(1-t)^2}{2D(i-g)^2} < 0,$$

[1] The variables B and z are equivalent to π_b and $\tilde{z}$ in Pratt's notation.

[2] Since the bid price is defined as the largest amount a decision maker will pay for a risky asset, the solution value for B in equations (5) and (9) requires selection of the positive square root. Selection of the positive square root in turn establishes the sign of $\partial B/\partial\sigma_y^2$ in equation (11) to be negative. Finally, it can be demonstrated that requiring the solution value of B to be real causes the sign of $\partial B/\partial r(x)$ in equation (12) to be negative.

where

$$D = \left\{\frac{1}{[r(x)]^2} - \left[\frac{(1-t)}{(i-g)}\right]^2 \sigma_y^2\right\}^{1/2},$$

$$(12) \quad \frac{\partial B}{\partial r(x)} = \frac{1}{[r(x)]^2}\left\{1 - \frac{1}{Dr(x)}\right\} < 0,$$

and

$$(13) \quad \frac{\partial B}{\partial x} = \frac{r'(x)}{[r(x)]^2}\left\{1 - \frac{1}{Dr(x)}\right\} \gtreqless 0.$$

The sign of $\partial B/\partial x$ depends upon whether the decisionmaker exhibits an increasing, unchanged, or decreasing degree of risk aversion over wealth, as determined by the sign of $r'(x)$.

$$(14) \quad \frac{\partial B}{\partial t} = -\left[\frac{E(y)}{(i-g)} - \frac{(1-t)\sigma_y^2}{D(i-g)^2}\right] \gtreqless 0.$$

The sign of $\partial B/\partial t$ is ambiguous because a change in the marginal tax rate influences the bid price in two ways. An increase in the marginal tax rate will decrease the bid price through a reduction in expected after-tax income from an acre of land, but increase the bid price through a reduction in the variability of after-tax income:

$$(15) \quad \frac{\partial B}{\partial i} = -\frac{(1-t)}{(i-g)}\left[\frac{E(y)}{(i-g)} - \frac{(1-t)\sigma_y^2}{D(i-g)^2}\right] \gtreqless 0,$$

and

$$(16) \quad \frac{\partial B}{\partial g} = \frac{(1-t)}{(i-g)}\left[\frac{E(y)}{(i-g)} - \frac{(1-t)\sigma_y^2}{D(i-g)^2}\right] \gtreqless 0.$$

The signs of $\partial B/\partial i$ and $\partial B/\partial g$ likewise are ambiguous without knowledge of the sizes of the parameters in the model. The effect of i and g on the bid price, however, will be of equal magnitude but opposite sign.

Interpretation of equations (10) through (16) leads to the following general results:

(*a*) A *ceteris paribus* increase in expected before-tax income resulting from economies of scale in production or marketing, more efficient management, specialization, or conglomeration will result in a higher maximum bid price per acre.

(*b*) A *ceteris paribus* increase in the variability of before-tax income resulting from greater degrees of operating or financial leverage or from additional exogenous uncertainty will result in a lower maximum bid price.

(*c*) A *ceteris paribus* increase in the degree of risk aversion resulting from changes in the parameters of the utility function will lead to a reduction in the maximum bid price.

(*d*) A *ceteris paribus* increase in the initial wealth position of the decisionmaker will result in a higher maximum bid price if the decisionmaker is decreasingly risk averse over wealth ($r'(x) < 0$). If the decisionmaker is increasingly risk averse ($r'(x) > 0$), an increase in the initial wealth position will result in a lower maximum bid price. If the decisionmaker's degree of risk aversion remains unchanged over wealth ($r'(x) = 0$), the bid price will be unaffected by an increase in the initial wealth position.

(*e*) A *ceteris paribus* increase in the marginal tax rate will, under reasonable assumptions about the sizes of the parameters in the model, lead to a reduction in the maximum bid price.

(*f*) A *ceteris paribus* increase in the decisionmaker's rate of pure time preference will, under reasonable assumptions about the sizes of the parameters in the model, lead to a reduction in the maximum bid price.

(*g*) A *ceteris paribus* increase in the decisionmaker's expected rate of growth of after-tax income will, under reasonable assumptions about the sizes of the parameters in the model, lead to an increase in the maximum bid price.

These conditions also can be interpreted in the specific context of potential future ownership of farmland. If it can be assumed that prospective buyers in the land market are decreasingly risk averse over wealth, land will be acquired by those bidders with (*a*) the highest expected before-tax income per acre (*b*) the lowest variability of before-tax income, (*c*) the largest initial wealth position, (*d*) the lowest degree of risk aversion, (*e*) the lowest marginal income tax rate, (*f*) the lowest rate of pure time preference, and (*g*) the highest expected rate of growth of after-tax income.

It is likely, however, that no bidder will

Table 1. 1969 Summary Characteristics of Iowa Cash-grain Farms and Farmers

Farm Class	0	I	II	III	IV
Average farm size (acres)	1,307	630	390	254	170
Net income per acre ($E(y)$)	\$36.18	\$39.16	\$33.95	\$26.67	\$19.04
Variability of net income (σ_y)	\$6.80	\$7.36	\$6.62	\$5.05	\$6.33
Marginal tax rate (t)	43%	32%	28%	25%	24%
Discount rate (i)	0.09082	0.09082	0.09082	0.09082	0.09082
Expected growth rate (g)	0.04387	0.04387	0.04387	0.04387	0.04387
Net worth (x)	\$234,167	\$117,489	\$99,953	\$98,568	\$47,616
Measure of risk aversion ($r(x)$)	0.00298	0.00594	0.00699	0.00709	0.01467
Per-acre bid price (B)	\$429	\$533	\$485	\$403	\$231

have an absolute advantage in all these categories. For example, decisionmakers with the highest expected income per acre may also be in the highest tax bracket. The ultimate winners in the land bidding process can be identified only with numerical specification of the parameters and variables in equation (9). The next section presents a numerical application of the model to cash-grain acreage in Iowa.

Farm Size and Bidding Potential for Cash-Grain Acreage

To demonstrate the applicability of the theoretical model to the issues of land ownership and control, maximum bid prices were estimated for various size categories of cash-grain farms in Iowa.[3] The size categories used were classes 0 to IV farms from the 1969 Census of Agriculture. For each of the classes, the Census indicates the total acreage, number of farms, and average size of farm. In 1969, for example, the average size of cash-grain farms in Iowa ranged from more than 1,300 acres for farms in class 0 to 170 acres for farms in class IV (table 1).

Data

Various sources of data were used in an attempt to define the characteristics of the average cash-grain farmer in each size category. Estimates were necessary for $E(y)$, σ_y, t, i, g, x, and $r(x)$ for each size classification.

The expected before-tax income per acre for 1970, $E(y)$, was based on the 1969 average as derived from Census data. Expected before-tax net income attributable to ownership of an acre of land was estimated by summing the market value of all agricultural products sold and receipts from government farm programs, subtracting total farm production expenses, and dividing the result by the total number of acres in cash-grain farms (table 2). Net income figures ranged from \$39.16 per acre for class I farms down to \$19.04 per acre for class IV farms (table 1). Economies of size resulted in increasing returns to size over classes IV to I. Moving from the average class I size farm to the average class 0 size, however, brought a reduction in net income per acre.

Variability of before-tax income per acre for each size class was estimated by using 1965–69 time-series data obtained from Iowa Farm Business Association records. The coefficient of variation was estimated for each size class in the Farm Business record survey and applied to the average net income figure for the appropriate size class in the Census scheme to give an estimate of the standard deviation of income, σ_y (table 1).

Taxable income per farm was estimated to determine the appropriate marginal tax rate for each size category. Total net income, as derived earlier, was divided by number of farms to get net income per farm for each size category (table 2). According to a study by Evenson, for Iowa farms during 1969 and 1970, taxable farm profits as reported by the Internal Revenue Service represented about 46% of net farm income as reported by the U.S. Department of Agriculture. Application of the 46% adjustment to net income per farm gave per-farm taxable income from farming for each size category (table 2).

Off-farm income for each class size was obtained from the Survey of Agricultural Finance—1970. This income includes reported receipts from all off-farm activities or sources of income, excluding government payments. Off-farm income per farm was added to taxable income from farming to get

[3] Cash-grain farms were used to avoid the complications of estimating income from livestock facilities that would accompany land in diversified farming areas.

Table 3. Class Size Characteristics and Bid-Price Differentials

Class Comparisons	Bid Price of First Class	Source and Size of Bid-Price Differentials: Net Worth	Marginal Tax Rate	Before-Tax Net Income	Net Income Variability
0–I	$429.08	$−10.09	$ 76.19	$ 43.16	$−4.96
0–II		−13.65	101.41	−34.20	1.99
0–III		−13.98	121.05	−151.92	18.75
0–IV		−39.84	107.50	−277.45	11.87
I–II	533.40	−5.93	28.55	−79.90	8.51
I–III		−6.49	49.67	−199.52	25.92
I–IV		−49.61	45.94	−325.69	27.13
II–III	484.63	−0.51	18.59	−116.29	16.56
II–IV		−39.61	20.28	−241.35	7.22
III–IV	402.98	−24.68	4.40	−123.51	−28.02
IV	231.17				

the classes rank from highest to lowest as I, II, 0, III, IV. The surprising result is that the largest class size, class 0, falls in the middle of the bidding-potential range.

To try to isolate the relative importance of the class size characteristics on the bid-price differentials between classes, bid prices were calculated by using incremental changes in characteristics. Results are shown in table 3. For example, line 1 of table 3 compares classes 0 and I. Column 1 gives the bid-price as $429.08 per acre for a decisionmaker with all class 0 characteristics. Column 2 shows that the bid price would decline $10.09 to $418.99 if the decisionmaker had all class 0 characteristics but had the net worth of a class I decision maker. Column 3 shows that the bid price would increase $76.19 to $495.18 ($429.08 − $10.09 + $76.19) if a decisionmaker with class 0 characteristics and class I net worth also had a class I marginal tax rate. Summing across line 1 for the 0 to I classes gives the class I bid price of $533.40.

Interpretation of the information in table 3 offers some general insights. If all decisionmakers have the same utility function, rate of pure time preference, and expected growth rate, and if the parameters and values used in the model are indeed representative of the characteristics of the various size classes, then the major sources of bid-price differentials are differences in before-tax income per acre and differences in marginal tax rates. Differences in net worth position and income variability, however, also have some influence.

Finally, the importance of size and the degree of risk aversion can be assessed by comparing the calculated bid prices with those that would pertain to a risk-neutral decisionmaker. If the decisionmaker is risk neutral, $r(x) = 0$, and the maximum bid price is that given by equation (9). Comparisons of calculated bid prices using the utility function given in equation (17) with those using any risk-neutral utility function are given in table 4. The difference between the bid prices represents the risk premium required by the decisionmaker. In general, the size of the risk premium increased as the farm size declined.[10] The bid prices for risk-neutral classes III and IV farmers are less than those for risk-averse classes 0, I, and II farmers.

Summary and Conclusions

The trend of the last two decades to larger and larger farming units has been viewed by many as a threat to the family farm. Disagreement exists as to whether that trend will continue. The analysis in this paper was based on the assumption that the future control of farming will be vested in those farmers with the greatest bidding potential for agricultural land. A

Census was $434 per acre. In an auction system, the market price will not be equal to the maximum bid price. Theoretically, it should be one bid unit higher than the second highest maximum bid price of the participants in the auction. The difference between the maximum bid price of the purchaser and the actual purchase price represents a form of consumer surplus that accrues to the purchaser.

[10] The notable exception is class III, where the risk premium declined. Derivation of the risk premium gives $\pi = 1/2\, r[x + E(z)]\, \sigma_z^2$ (Pratt, p. 125), where π is the size of the risk premium. Thus, the risk premium is a function of initial net wealth, the expected value of an acre of land and the variability of the value of an acre of land. The risk premium also can be defined as $\pi = \frac{r[x + E(z)](1 - t)^2}{2(i - g)^2}\sigma_y^2$. For class III farms, the variance of income σ_y^2 was substantially smaller than for the other categories. Hence, the smaller risk premium than for adjacent size classes.

Table 4. Required Risk Premiums per Acre

Farm Class	0	I	II	III	IV
Risk-averse bid price	$429.08	$533.40	$484.63	$402.98	$231.17
Risk-neutral bid price	439.25	567.17	520.64	426.04	308.21
Risk premium	10.17	33.77	36.01	23.06	77.04

theoretical model was developed to explore some of the important variables affecting that bidding potential, and a numerical example of the model was developed for cash-grain farms in Iowa.

The theoretical model was constructed to determine the maximum bid-price that would be made for an acre of land by a decisionmaker with a given set of characteristics, capabilities, and expectations. The variables included that have an impact on the maximum bid price are (*a*) before-tax net income per acre, (*b*) variability of income per acre, (*c*) initial net wealth position, (*d*) degree of risk aversion, (*e*) marginal income tax rate, (*f*) rate of pure time preference, and (*g*) expected rate of growth in land income and prices. As such, the model is capable of incorporating most arguments that are typically advanced for or against the continued growth of farming units.

The numerical example identified and estimated the average characteristics of Iowa cash-grain farmers in each of the Census farm size classes 0 to IV for the year 1969. These characteristics were inserted into the model to determine the maximum 1969 bid price by the average farmer in each class. Estimated bid prices ranged from a high of $533 per acre for class I to a low of $231 per acre for class IV.

Although the results of the numerical example must be interpreted with caution, they do provide some insight. First, it seems that the largest farms may not have the greatest bidding advantage after all. A combination of higher marginal tax rate and diseconomies of size may cause class 0 farmers to have a lower maximum bid price than either class I or class II farmers. Or, interpreted differently, if class 0 farmers are to consistently outbid smaller farmers, they must have a lower degree of risk aversion, a lower required rate of return on investment, or a higher expected growth rate for income and land prices than smaller farmers. If all farmers have the same utility function, the same required rate of return, and the same expected growth rate (as we have assumed in the model), it seems that the greatest threat to the small family farm is the larger family farm.

The results of this study are consistent with the conclusions of Krause and Kyle regarding the importance of economies of size and tax incentives in the growth of farming units. In addition, however, the results indicate that wealth position, income variability, and the degree of risk aversion are important considerations for the issues of the ownership and control of farmland. If public policy is intended to "save the family farm," it may be necessary to devise schemes to deal with all these factors.

Small farmers may be at a particular disadvantage in their attempt to bid away land from their larger neighbors. For example, even if classes III and IV farmers are risk neutral, the results of the study imply that they may have lower maximum bid prices than risk-averse classes 0, I, and II farmers. Thus, policies designed to shift the burden of risk away from small farmers, in and of themselves, may be inadequate to make those farmers competitive in the land market.

The analysis in this study points out the potential for additional work at both the theoretical and empirical level. While the theoretical model represents a start in formulating the bidding potential of investors in farmland, much work is yet to be done. Since domestic and alien nonfarm investors are important potential participants in the land market, and since some farmers may have substantial off-farm investments, it would be especially fruitful to extend the model to capture the impact of diversification on bidding potential. Also, the model could be adapted specifically to investigate the influence of public policy variables such as acreage restrictions, differential property tax rates, and differential income tax rates.

The attempt to generate meaningful estimates of decisionmaker characteristics, capabilities, and expectations painfully demonstrates the need for additional data. One must be especially uneasy with the shortcomings of some of the data used in the numerical illustration. The necessity to use aggregate census data for generation of income estimates, to use a different source for income

variability, to assume the proportion of taxable income to net farm income is the same for all farm-size classes, and to assume that all classes of farmers have the same utility function leaves the researcher most anxious for new and better data sources.

In a resource-scarce environment, it is necessary to establish priorities on data gathering efforts. The preliminary results of the numerical illustration suggest that better measurements of net income and effective marginal tax rates across investor classes are of primary importance. An evaluation of the impact of degree of risk aversion on bidding potential suggests that measurement of investors' utility functions is also a priority item for this and other research. Hopefully, this study offers some encouraging incentives for researchers in those areas. The issues of ownership and control cannot be completely resolved until more accurate and complete specifications of the important parameters are made.

Landowner Benefits from Use-Value Assessment under the California Land Conservation Act

S. I. Schwartz, David E. Hansen, and T. C. Foin

The factors that determine the size of benefits to landowners who participate in the use-value assessment program under the California Land Conservation Act are identified, and the level of benefits available to landowners is calculated for several cropping patterns in Sacramento County. Possibilities for decisionmakers to increase participation by altering benefits is examined through a sensitivity analysis on the factors that determine benefit levels. It is concluded that little opportunity exists for decisionmakers to influence enrollment significantly except through measures that influence land values or development expectations of landowners.

Key words: agricultural land preservation, land use, preferential taxation, property taxes, use-value assessment.

Use-value assessment programs, whereby land is taxed at its agricultural rather than market value, provide property tax relief to landowners in at least thirty five states (Gloudemans). In some states, e.g., California, such programs are explicitly directed at reducing the rate of conversion of agricultural lands to urban uses (Henke, California Legislature). The use-value assessment legislation that is embodied in the California Land Conservation Act (CLCA)[1] has three major objectives: to reduce undesirable sprawl resulting from the "premature and unnecessary conversion of agricultural land to urban uses," to maintain lands in agricultural use for their open-space value, and to preserve agricultural land in production to assure an adequate food supply and healthy agricultural economy (*California Government Code,* Sec. 51220).[2]

To obtain benefits under the CLCA, a contract is required between the landowner and the county or city, by which the land is maintained in agricultural or open-space use for a specified minimum period. Once a contract is in effect, it may be terminated either by nonrenewal or by cancellation. With a ten-year contract, notice of nonrenewal may be given at any time after the end of the first year. The contract then continues for nine more years (the runout period) with assessments rising to full market value by the termination date. Lacking notice of nonrenewal, another year is added to the contract term each year, so that it continues to maintain the use restriction for ten more years. Under special circumstances, which are judged to be in "the best public interest," a contract can be cancelled immediately and thus not be subject to the runout period.[3]

To significantly reduce the rate of land conversion through contract enrollment, benefits of reduced property taxation accruing to landowners must be large enough to induce holding of the land in agriculture longer than if market value taxation were used. The size of the present value of future use-value taxation benefits depends on a number of important

Giannini Foundation Paper No. 409.

[1] The California Land Conservation Act of 1965 is widely known as the Williamson Act.

[2] Possible areas of conflict between these expressed goals have been discussed elsewhere (e.g., see Stanford Environmental Law Society). For purposes of this study, it is assumed that the intent was not to prevent all conversion of agricultural land to urban use but rather to discourage sprawled development of a leapfrog nature.

[3] Our analysis assumes that contract terminations are by nonrenewal. Specific requirements for contract cancellation are stated in *California Government Code*, Sec. 51282. A detailed discussion of the provisions and implementation of the Act may be found in Wagenseil.

parameters in addition to the difference between market and use value of the land. In this paper, six additional factors that determine the level of benefits are examined: future agricultural income, length of the contract period, property tax rate, discount rate of the landowner, discount rate in the runout formula,[4] and the reassessment time lag, i.e., the number of years elapsing between county reassessments.

This paper examines the impact of selected factors on benefit levels and thus the incentives to farmland owners to sign contracts under the CLCA. Some of the parameters that are examined can be altered by policymakers, while others are determined by the broader economic milieu. Although it is difficult to determine accurately the elasticity of contract enrollment to increased contract benefits, the results of the study provide some basis for policymakers, who are trying to influence enrollment by altering benefits, to select from among parameters under their control. The impact of exogenous factors (assuming lack of compensating actions by policymakers) is also examined.

Using data from a detailed parcel analysis of Sacramento County, the present value of the stream of reduced taxes is calculated as the measure of the incentive for the landowner to accept a contract. The effect of variations in the parameter values on the present value of contract benefits is explored to determine the sensitivity of benefits to parameter variations.

Calculation of CLCA Enrollment Benefits

Current Annual Tax Reductions

Three areas of Sacramento County were chosen for analysis based on their proximity to urban development and their diversity of agricultural activities. Market-value assessments were obtained from the county assessor's office for all parcels over twenty acres, and use-value assessments (CLCA assessed values) were obtained for the 113 parcels actually under contract. For the 678 noncontracted parcels, the use-value assessment was calculated by the capitalization of rental income method used by assessors throughout the state. The tax reduction was determined by multiplying the parcel tax rate by the difference between market and restricted-use assessed values.[5]

Present Value of Total Contract Benefits

The present value of contract benefits is calculated from estimated future annual tax reductions, which are based on current values of market and use-value assessments and an assumed land price pattern. The annual benefit, net of federal and state income tax payments, is calculated from

$$(1)\quad B_i = (AVM_i - AVR_i)\,(PTR_i)\,(1 - ITR),$$

where B_i = property tax benefit per acre in year i, AVM_i = estimated market assessed value in year i without a CLCA contract, AVR_i = estimated assessed value under CLCA contract in year i, PTR_i = estimated property tax rate in year i, and ITR = combined federal and state income tax rate.

For purposes of this study, a combined federal and state income tax rate of 40% is assumed. The assessment process is simulated by assuming a time lag between reassessments, during which time the assessed market value of the land is assumed to remain constant. The assessed value of land under contract (AVR) is estimated for each year from the initial CLCA-assessed values and from assumptions about changes in agricultural income. AVR is equal to the agricultural assessed value of the land ($AVAG$) until a notice of nonrenewal is given, at which time AVR is calculated from equation (2), which is specified in *California Revenue and Taxation Code*, Section 426(b):

$$(2)\quad AVR_i = AVAG_i + (AVM_i - AVAG_i)\,\frac{1}{(1 + r_s)^{T-i}},$$

where $AVAG_i$ = agricultural assessed value in year i, calculated by the capitalization of income method, r_s = the discount rate established by the state for use in the runout calculation (revised each year according to long-term bond rates), T = total number of years in contract period, and $T-i$ = number of years until contract expiration.

[4] The discount rate in the runout formula is set by the state each year according to long-term bond rates.

[5] The restricted-use assessed value is the assessment under CLCA contract and is determined from the agricultural rental value of the land, except during the runout period when it is determined according to equation (2).

Table 1. Initial Values Used in Sensitivity Analysis

	Rice	Dry pasture	Irrigated crops
Market assessed value/acre[a]	$254.25	$89.68	$188.67
Agricultural (CLCA) assessed value/acre[b]	91.41	17.55	96.04

[c] Average values for each cropping pattern.

Analysis of Results

To examine the variation of program benefits to the landowner, a set of initial values for market and agricultural (CLCA) assessed value of the land, agricultural income, and property tax rate was defined for each cropping activity (see table 1). Cropping activities selected included rice, dry pasture, and the combined category of irrigated pasture and row crops (hereafter called "irrigated crops" for brevity). Initial values were based on actual data from the County Assessor's Office for noncontracted land. A set of baseline conditions was then specified for the seven parameters that determine the level of contract benefits. The baseline conditions and the variations of the parameters employed in this study are presented in table 2. The present value of benefits was calculated for the baseline conditions and for each change from the baseline condition, thereby providing an indication of the relative importance of the selected parameters and parameter combinations.

Current Annual Benefits

The estimated annual tax benefits for contracted lands and the potential benefits that could be obtained by enrollment of parcels not now under contract are summarized in table 3 according to cropping pattern. It is seen that the percentage reduction in the tax bill is sizable, ranging from 49% for irrigated crops to 80% for dry pasture for the noncontracted lands, and from 40% for irrigated crops to 72% for dry pasture for contracted lands. For dry pasture, the annual benefits of $5.76 for contracted land and $9.15 for noncontracted land exceed the rental value of $4 to $5 per acre, an indication of the large relative benefits that are attainable under the Act.

The larger percentage reductions available for noncontracted lands for all crops studied are due to the higher market values of noncontracted lands. Market values of noncontracted lands exceed those of contracted lands by between 18.8% (for irrigated crops) to 35.8% (for dry pasture). One possible explanation is that the noncontracted parcels contain a larger "urban increment" in their price and that owners did not enroll despite potentially larger

Table 2. Baseline Parameter Values and Variations Used in Sensitivity Calculations of CLCA Benefits

Parameter	Baseline	Variations from baseline
Market assessed value of land	6 %/year increase	3 %/year increase 10 %/year increase
Future agricultural income	initial values[a]	6 %/year increase 50 % initial increase
Contract length	20 years	10 years 30 years
Property tax rate	initial values[a]	1 %/year increase 3 %/year increase
Landowner's discount rate	8 %	6 % 10 %
Run-out formula discount rate	6.75%	5.75% 7.75%
Reassessment lag	3 years	1 year 2 years 4 years

Note: These baseline parameters and the variations were applied to all crops.

benefits because of the greater developmental potential of their land. Low enrollments close to urban areas have also been reported by Carman and Polson, Barron and Thomson, Gloudemans, and Gustafson.

Sensitivity of Present Value of Benefits

Variations in contract benefits due to changes in each of the seven factors that determine benefits are compared to baseline conditions in table 4. The present values of benefits for nonbaseline conditions and the percentage deviation from the baseline values are shown for rice, dry pasture, and irrigated crops.

An increase in the rate of land appreciation from 6% to 10% (with other baseline conditions held constant) caused the value of benefits to increase from 25.6% for dry pasture to 36.2% for irrigated crops. Conversely, an increase in land values for only 3% per year decreases benefits by 15.5% for dry pasture and 21.1% for irrigated crops. Thus, benefits are found to vary considerably in response to changes in land value appreciation.

This analysis examines only the sensitivity of benefits to changes in rates of land value appreciation. It does not address the question of whether or not a contract should be accepted under these price patterns when the opportunity costs associated with the loss of a possible sale is considered. Further discussion of this issue is in the concluding section.

Contract benefits are very small for a contract that is in force for only the minimum ten-year period. When the present value of per acre tax savings are expressed as percentages of the initial values of the land, the largest present value of benefits was only 3.9% of the initial value of rice land and the smallest value was 2.4% of irrigated crop land. This result is explained by the nature of the runout formula, which is applied upon notice of nonrenewal. For a ten-year contract, with notice of nonrenewal given at the end of the first year, the assessed value would increase by about 60% of the difference between market- and use-value assessments. The full benefit of use-value assessment would be obtained only in the first year. If a contract is held for twenty years, benefits are substantially greater (from 11.1% of the initial land value for irrigated crops to 16.4% for dry pasture), since full benefits are received for eleven years.

For the thirty-year contract, the present value of benefits varies from 20% to 27.4% of initial land value for irrigated crops and dry pasture, respectively. The thirty-year contract benefits are greater by 67% (dry pasture) to 81% (irrigated crops) than those of the baseline conditions. Thus, the benefits of contract acceptance are highly sensitive to changes in contract length and can be substantial if the contract is held for a long enough period of time.

The effects of landowner discount rates of 6% and 10% were compared to the 8% rate assumed in the baseline calculations. At 6%, benefits increased by approximately 15% for all crops, whereas at 10%, benefits decreased by about 12%.

The effect of a change in the discount rate used in the runout formula, equation (2), is opposite in direction to that produced by a change in the land-owner discount rate. A de-

[a] Baseline values by cropping activity are from table 1.

[b] The state discount rate is the rate specified for the calculation of property taxes during the runout phase of the CLCA contract (see equation (2)).

crease of one percentage point in the runout formula (from 6.75% to 5.75%) produces a lowering of benefits of only about 1.8% for all crops. The effect of a one percentage point increase in this discount rate is opposite in direction and is of the same magnitude as the one percentage point decrease. Thus, it is seen that both the landowner discount rate and the runout formula discount rate produce small impacts on the levels of contract benefits.

Changing the reassessment time lag from the baseline value of three years to the shortest feasible lag of one year increases the benefits by between 7% (dry pasture) to 9.8% (irrigated crops). A lag of two years increases the benefits by only 3.1% and 4.4% for dry pasture and irrigated crops, respectively, whereas a lag of four years decreases benefits by approximately the same amount. It is concluded that more frequent reassessment of parcels would have little effect on contract benefits.

A 1% per year increase in the property tax rate results in increased benefits from 6.4% (dry pasture) to 6.8% (irrigated crops). A 3% per year increase in the property tax rate increases the benefits by approximately 21% for all crops studied. Although the absolute tax bill of the landowner increases with increasing property tax rate, the contract benefits (relative to the no-contract situation) also increase. Since a 3% annual increase would almost double the property tax rate in twenty years, there is some question as to whether such a rate of increase could be sustained. Accordingly, changes in property tax rates are felt to have limited potential for influencing the level of benefits under the CLCA.

Increases in agricultural income, if not fully capitalized into increases in market value, reduce the difference between market and use-value assessment, and hence the size of the CLCA benefits. Income is the only variable to cause considerable between-crop differences in benefits. A 6% per year increase in agricultural income caused less than a 7% decrease in benefits for dry pasture but a 24% decrease for irrigated crops. An initial increase in income of 50% produced a similar pattern, with benefits for dry pasture decreasing by only 8.8%, while those for irrigated crops decreased by 32%. Changes in rice benefits fell between these values for both income changes. Since the CLCA agricultural assessed values depend on agricultural income, the differences in benefit changes among the crops can be explained by the ratio of agricultural to market assessed values, with the largest change in benefits occurring for the smallest ratio of agricultural to market assessed value.

Sensitivity of Benefits to Interactions of Selected Factors

Two criteria were established as the basis for selecting among the many possible combinations of factors that influence the present value of CLCA benefits: the degree to which the parameters are controllable by policymakers, and the impact on benefits as determined by the single variable sensitivity analysis of the previous section. The parameters are classified into three categories in terms of policymaker control: those directly controllable by policymakers, those partially controllable, and those not controllable. Factors under the control of policymakers are the contract length, reassessment lag, and the discount rate used in the runout formula. Variables largely beyond the control of decisionmakers are the agricultural income and the landowners' discount rate, while the property tax rate and market value appreciation of land form an intermediate category, since they are usually determined by broader economic forces but can be influenced by policymakers.

Based on the single variable sensitivity analysis, only two variables are considered to have significant potential for influencing the present value of benefits: contract length and the market value appreciation of land. The landowner and runout formula discount rates and the reassessment time lags are found to be of little significance, while the remaining variables (property tax rate and agricultural income) are found to have a limited impact on benefits. Based on these criteria, the logical candidates for interaction analysis are contract length, land values, and (to a lesser extent) the property tax rate.

As seen in table 5, changes in appreciation in market value under a ten-year contract have little impact on benefits, compared to the ten-year contract results of table 4, indicating the dominant effect of the ten-year contract. By contrast, a strong interactive effect is demonstrated when a thiry-year contract is combined with a 10% increase in land values, with benefits increasing from two to two-and-one-half times the highest levels demonstrated in any of the single variable sensitivity results. Benefits are approximately three times the baseline values when a thirty-year contract is combined with a 10% per year appreciation in market value of land. This represents an increase in benefits of from 62% (dry pasture) to 86% (irrigated crops) over the additive effect of the two variables.

The effect on benefit changes is noticeably diminished when contract length is considered together with the property tax rate rather than with land value appreciation. However, with a thirty-year contract, the effect of the property tax rate is still significant. Benefits are approximately double the baseline values when a 3% increase in the property tax rate is added. This increase in value is approximately 50% above the additive effect of the two factors taken separately. By contrast, a ten-year contract provides essentially the same level of benefits regardless of the change in property tax rate.

When the appreciation in market value of land and the changes in property tax rates are taken together, the results are approximately the same as the individual additive effects. For low rates of appreciation in market value of land, the decrease in benefits are in part counteracted by the effect of increased property taxes, with results within 5% of what would be obtained by adding the individual impacts. The same result is observed for the higher rate of land appreciation with the low property tax rate increase. Slight interactive changes result when the high land appreciation rate is combined with the high property tax increase. Benefits are approximately 10% less than would be true for a strictly additive impact. We are able to conclude that for higher rates of land appreciation and property taxes benefits under the CLCA can be substantial (and addi-

tive), ranging from 55% to 71% above the baseline conditions for dry pasture and irrigated crops, respectively.

Conclusions and Policy Implications

For the land values and incomes prevailing in the study area, the acceptance of a CLCA contract can reduce the tax bill of a landowner by as much as 50% to 80% for the crops analyzed. However, the present value of contract benefits does not become substantial unless the contract is held for twenty years or more. For a minimum term contract of ten years, the benefits are always less than 5% of the initial land value.

Because a long-term contract commitment is required to obtain substantial CLCA benefits, the opportunity costs associated with foregoing a favorable sale assume particular significance. This is especially true since results presented in this paper indicate that unenrolled lands show a higher potential tax benefit than enrolled lands—suggesting that the enrollment decision is influenced by other than simply the size of current tax reductions.

Because a wide variety of land price patterns and assumptions about the timing of sale are possible, determination of whether contract acceptance is justified is complex and does not lend itself easily to calculations of "break-even" benefit levels. In a previous study (Schwartz, Hansen, and Foin), opportunity costs were examined by comparing the present value of contract acceptance (assuming sale of land at the end of twenty years) to the present value of nonacceptance and sale during the twenty-year period. Several general conclusions emerged. If the rate of price increase is above the landowners' discount rate

and the increase continues throughout the contract period, the contract alternative is preferred. Nonacceptance of a contract was favored for sharply peaked patterns wherein the local maximum in the present value of the noncontract alternative created by the price peak exceeded the present value of the land plus contract benefits at the end of the twenty-year period. However, if the sale was not assumed to be reasonably close to the peak, contract acceptance was often favored.[6] Furthermore, modest price increases occurring after the peak could also cause the contract alternative to become the preferred choice. Our analysis indicated that a substantial number of situations were likely to favor contract acceptance.

In a second study (Hansen and Schwartz), we found enrollment rates at the rural-urban fringe to be much lower than would be expected if enrollment decisions had been based on a long-range economic comparison of the alternatives. Our conclusion, based on the economic analysis and surveys of landowners, was that unrealistic land development expectations were held by a large proportion of landowners at the urban fringe.

One possibility for making the CLCA contract relatively more attractive to the landowner is to increase benefits directly—an approach that is likely to entail considerable tax shifting. As an alternative, the levels of CLCA benefits could be altered by changes in the parameters that determine these benefits. Of those parameters under the control of policymakers, the reassessment lag and runout formula discount rate were found to have little impact on levels of benefits. Only the length of contract was found to be of significant influence. A twenty-year contract yields benefits that are as much as 300% greater than those from a ten-year contract. However, previous research has shown that substantial enrollment is lost (or would be lost) by longer minimum term contracts (Schwartz et al.). Since a ten-year contract is extended each year unless a notice of nonrenewal is filed, there is no need to offer contracts of longer minimum term. The shorter minimum term provides greater flexibility to the landowner, while allowing the same level of benefits to be reached through renewal. Thus, policymakers who wish to encourage greater enrollment should implement the shorter term renewable contracts.

Agricultural income and the landowners' discount rate are variables largely beyond the control of decisionmakers. Although land-use control policies can alter agricultural income to some degree and can affect the discount rate by affecting the uncertainty of permissible land uses, these variables are primarily determined by broader economic conditions. Our results indicate that policymakers need not be greatly concerned with changes in these exogenous variables. Quite large changes in the landowner's discount rate are required before a noticeable impact on benefits occurs. Although large increases in agricultural income are seen to reduce benefits substantially in some cases, the net effect is probably to lessen the pressures to sell prematurely.

The property tax rate and land value appreciation variables are usually determined by broader economic forces but can be influenced by policymakers. Benefits are only moderately sensitive to changes in the property tax rate, with the higher levels noted in the property tax-contract length interactions being largely attributable to the contract length. Since the property tax rate is an extremely blunt instrument for influencing enrollment, and since an increase in the rate will produce a larger actual tax bill for the landowner (along with the relative increase in benefits), such a measure has little appeal for influencing benefits. Land values can have a major impact on the level of benefits, with interactions with property taxes and contract length also producing marked increases. However, the limitations of these latter two variables for policy purposes should again be noted.

The results of this study lead us to the conclusion that there is little opportunity for policymakers to influence enrollment (other than by altering direct benefits) except through measures that influence land values or the development expectations of landowners. Development expectations could be altered by providing greater information about the CLCA and land price trends. Alternatively,

[6] As examples, assuming agricultural income of $60 per acre and a land price that increases at a rate of 10% per year, land with an initial value of $1,017 per acre, when held for the twenty-year contract period, has a present value of $2,691 (including CLCA contract benefits and income). In contrast, if noncontracted land undergoing the same price changes was sold in year 10, and the proceeds, less capital gains taxes, were reinvested at an after-tax return of 6%, the present value would be $1,734. If the price pattern exhibited a 5% to 10% increase through year 6, a 50% increase in year 7, then a drop to year 6 levels, the sale at optimal time (year 7) would produce a present value of $1,780 for noncontracted land. If, instead, sale was in year 5 instead of year 7, the present value of noncontracted land would be only $1,297. These compare with $1,387 for contracted land.

more stringent land-use regulations could be implemented. However, to the extent that more effective planning and enforcement of zoning is required to decrease expectations and produce greater enrollment under the CLCA, the use-value assessment, by itself, must be considered to have little potential for effectuating desired land use patterns at the urban fringe.

An Economic Analysis of a Regionalized Rural Solid Waste Management System

William E. Hardy, Jr., and Curtis L. Grissom

A quantitative model is developed to examine the possibility of cost savings through cooperative efforts in collecting and disposing of solid waste material. Heuristic algorithms are used to determine the best locations for landfills and the best routes for the collection trucks to follow in serving the five-county study area. The results of the economic analyses indicate that a regional system for solid waste collection and disposal can be justified from a cost standpoint.

Key words: location analysis, regional planning, solid waste management, vehicle scheduling.

The availability of adequate public services such as solid waste disposal systems, sewer and water systems, transportation networks, quality education, and medical care is a prime factor affecting the development of many rural areas. In some localities, necessary services are not available, or if they are present, they are of very low quality. Many sparsely populated rural areas, because of their low income base, simply cannot afford to provide adequate levels of all needed services and, as a result, will likely remain poor and underdeveloped.

Emphasis is presently being placed upon the concepts of regionalism and community cooperation in planning for the provision of certain public services. Legislation passed in recent years at both the federal and state level has been designed to encourage such cooperative efforts among local governing bodies so that unnecessary duplication might be avoided and better quality services provided.[1]

Renewed interest has been generated among researchers regarding public service delivery problems. Jones and Gessaman present a brief survey of recent research in this area with emphasis directed toward those studies investigating possible cost reductions through consolidation of local governmental efforts. They indicate that the findings of these efforts point to lower costs through economies of scale up to certain levels for most services but that consolidation cannot be supported as a universal means for reducing costs. In a study examining the solid waste management problem, Schreiner, Muncrief, and Davis found that there are significant economies of size in the disposal process, but the the cost of collection was more closely related to customer density than to the size of the service area.

This paper continues the discussion of rural public service delivery problems through presentation of the results of a research project designed to determine the least cost solid waste management system for a selected five-county area of northwest Alabama. The study area, Alabama Regional Planning District 1, is predominately rural with a single urbanized area located in portions of two of the counties. The data presented in table 1 give the geographic area, population, and expected annual solid waste for the five counties considered. This multicounty area is typical of many regions of the United States, thus the results of the research could be applicable nationwide.

The Theoretical Model

The basic computational logic followed in the analysis was to develop a set of feasible solu-

William E. Hardy, Jr., is an assistant professor of agricultural economics at Auburn University, and Curtis L. Grissom is a district farm agent with the Cooperative Extension Service at the Virginia Polytechnic Institute and State University.

The research on which this report is based was carried out under Hatch Project Alabama-363, entitled "Solid Waste Management for Northwest Alabama Using Sanitary Landfills."

[1] The Housing and Community Development Act of 1974 and the Rural Development Act of 1972 are federally sponsored laws that have sections encouraging cooperative efforts. Individual states have laws permitting or requiring regional planning districts. In Alabama, Act 1126, passed in 1969, created such organizations.

Table 1. Area, Population, and Expected Annual Solid Waste for Counties in Alabama Regional Planning District 1

County	Geographic Area (sq. mi.)	Population Rural	Urban	Total	Expected Solid Waste (tons)
Lauderdale	661.8	34,080	34,031	68,111	249.59
Colbert	596.4	20,782	28,850	49,632	189.61
Franklin	643.9	16,119	7,814	23,933	86.90
Marion	743.0	17,547	6,241	23,788	84.78
Winston	633.0	12,520	4,134	16,654	59.10

Source: Area and population data are from *County and City Data Book, 1972* (U.S. Dep. of Commerce). Expected solid waste data were obtained by multiplying population by appropriate waste generation coefficients (Muhich).

tions, calculate the total cost for each, and then compare these to determine the least cost organizational pattern. This is similar to the plant location and assembly cost concepts presented earlier by Stollsteimer and later modified by Chern and Polopolus.

Each feasible solution and resulting total cost data was obtained through the use, in a stepwise fashion, of two basic quantitative models. First, a location model was used to determine the best locations for specified numbers of sanitary landfills. Second, a routing algorithm was employed to determine the best routes for collection trucks to travel in collecting the solid waste for each locational pattern established by the first model. The authors realize that better solutions and further cost savings for the given problem might be realized through a simultaneous or iterative use of the two models; however, such methodology is currently unavailable.

The Location Model

The problem involved in determining the best locations for specified numbers of sanitary landfills can be referred to the general class of theories and models known as the "location-allocation problem." With these problems, the best locations for specific numbers of central facilities are to be found, and the assignment of the flows of goods between these facilities and another set of points is to be determined. If the locations are already known, then the flow assignment problem becomes the ordinary linear-programming transportation problem. The classical spatial economics problem presented by Weber (Friedrich) can handle the pure locational problem that exists if the flow assignment is known, but the location of the central facility is unknown.

Scott presents a detailed explanation of the basic and extended location-allocation systems and discusses appropriate methodology for solving these problems. Optimizing methods are available, but he emphasizes that "location-allocation problems are frequently soluble by heuristic programming" (p. 111). This is particularly true for large scale models.

The model used to determine the best locations and pickup point assignment for this research was based upon the heuristic procedure presented by Shannon and Ignizio and programmed by Hardy (1973). The objective of minimizing total transport miles may be presented as

$$(1)\quad \min TTM = \sum_i \sum_j [[C_{ij}(X_{ij})]\,[Z_{ij}Y_j]].$$

This objective is consistent with the "central place" theories and gravity models used by economic geographers and market planners (ReVelle and Swain) in using distance as a surrogate measure for cost. The C_{ij} values represent the distance that each unit of solid waste, X_{ij}, must be transported from collection point i to sanitary landfill j, while Z_{ij} is a zero-one variable that takes on a positive value if waste from i is transported to j. The variable Y_j is also zero-one, being nonzero if a landfill is located at j.

Attainment of the objective was limited by the constraints

$$(2)\quad \sum_j X_{ij} \geq D_i,\ (i = 1, 2, \ldots, M),$$

$$(3)\quad \sum_j Y_j \leq F,$$

and

$$(4)\quad \sum_j Z_{ij} \leq 1,\ (i = 1, 2, \ldots, M).$$

Equation (2) assures that the total waste, D_i, at all M pickup points is collected. The con-

straint value, F, in equation (3) specifies the number of landfills to be located, and equation (4) prevents the waste from each pickup point from being delivered to more than one landfill—no multiple delivery points.

The complete location analysis required the assimilation of several types of data. Information concerning the location and quantity of waste to be collected, the location of potential landfill sites, and the most direct road distances connecting all waste collection points and potential landfills sites had to be obtained.

Census enumeration district data and maps giving population distribution and density for the total study area were combined with national average coefficients (Muhich), giving expected daily waste generation for rural and urban areas, to calculate the amount and location of residential waste that could be expected from the households of the area. National average waste generation values were used because the five counties considered in the study did not have accurate data to reflect their actual collection volume.

It was assumed that individuals would deposit their solid waste in containers at one of 237 collection points that were selected on the basis of population location and density and that collection trucks would service these containers twice weekly. It was necessary to assume that a containerized collection system would be used, since determining the location of each house and designating it as a pickup point would have been practically impossible and computationally infeasible. It was assumed that one or more containers would be placed at each collection point with the number of containers being dependent upon the expected amount of waste for that area.

General soils maps prepared by the U.S. Department of Agriculture Soil Conservation Service were utilized to determine potential landfill sites (Muscle Shoals Council of Loc. Govt.). These maps indicated areas within the five-county region that were geologically suited for landfills. Thirty-four potential sites were specified.

County highway maps were used to determine the most direct all-weather routes connecting all collection points with each other and with each potential landfill site. The distances from each point to all adjacent points were measured manually from the maps. All other connecting distances were obtained by using a computerized shortest-path algorithm (Hardy 1972). A total of 73,441 (271 × 271) connecting distances were required for the complete analysis.

The objective in determining the best locations for each of the specified number of sanitary landfills was to establish those locations that would minimize total travel if a single trip was required to deliver the waste from each collection point to the sanitary landfill. Thirty separate location analyses were completed, giving the best single, two, and three sanitary landfill locations for each county and for three subregional multicounty combinations. Subregional multicounty combinations were considered because it was felt that cooperative efforts could exist among areas smaller than the regional level. The best locations for one through six landfills were found for the five-county region taken as a whole. In addition to indicating where each landfill should be located, the location analysis permitted the determination of the service area boundaries and the necessary size for each landfill to accommodate the expected waste from the area for ten years. These landfill capacity needs were estimated using guidelines established by Carley.

The Routing Model

A substantial portion of the total cost of operating a solid waste management system is incurred during the collection process (Huie). Because of this, it is imperative that collection vehicles be used as efficiently as possible. The problems encountered in designing an economically efficient collection system are normally classed with the theories referred to as "transportation-routing problems." In this problem area, the decisionmaker must schedule an existing fleet of vehicles, each with a capacity constraint, to visit a set of stops or destinations and pickup or deliver goods or services at each stop such that only one vehicle visits each stop. The objective is to minimize the total cost of delivery. Normally, it is assumed that cost is proportional to distance.

A detailed survey of the current state of the art regarding routing problems is presented by Turner, Ghare, and Fourds. Turner and his associates point out that there are models available that will give optimal solutions to vehicle-scheduling problems, but that for these methods computational time increases exponentially with problem size.[2] Because of

[2] They further indicate that most of these models that guarantee optimality are based upon the conventional "traveling salesman

this limitation, most large-scale problems, as with location-allocation problems, have been solved heuristically. One of the first and most extensively referenced of such models was developed by Clarke and Wright. Their heuristic procedure has served as the basis for many successful applications.

A computerized routing algorithm developed by Hallberg and Kriebel and based upon the Clarke and Wright method was selected for use in the routing-analysis section of this study. The program permits great flexibility in problem formulation and is computationally efficient. The basic logic followed by the procedure in route development is as follows. The maximum cost solution is first assumed. With this assumption, all pickup points or stops are each placed on individual routes so that the total cost would be

$$(5) \quad TC = 2 \sum_j C_{oj}$$

for symmetrical problems, and

$$(6) \quad TC = \sum_j C_{oj} + \sum_j C_{jo}$$

for asymmetrical problems. In equations (5) and (6), C_{oj} and C_{jo} represent the relevant costs of travel from the origin to a stop and from a stop to the origin, respectively.

The next step is to develop savings coefficients, S_{ij}, which represent the amount of savings if two stops are joined on a route. The savings for connecting stops i and j would be

$$(7) \quad S_{ij} = C_{io} + C_{oj} - C_{ij}.$$

Savings coefficients are calculated for all possible combinations of stops taken two at a time and arranged in descending order. Route development then begins with pickup points being linked to a route on the basis of maximum savings coefficients. For the solid waste management problem considered by this study, points were added to routes until either truck capacity (thirty cubic yards) or travel time (eight hours) or both were violated. A more detailed explanation of the computation procedure is presented by Schruben and Clifton.

A truck-routing analysis was completed for each sanitary landfill locational pattern established by the location model. In addition to generating the best collection routes, these routing analyses aided in determining how many trucks would be required for each landfill operation and the total number of miles that each would travel. This information was necessary for establishing total investment and operating costs involved in the collection process.

problem" and rely upon the techniques of integer and dynamic programming and branch and bound programming.

Research Results

The results of the thirty location and routing analyses provided input for budgets that were prepared to permit cost comparisons for each alternative solid waste management system. The data presented in table 2 illustrate the total initial investment and annual operating cost data for specified numbers of sanitary landfills in each individual county, each multicounty subregional system, and the total five-county region.

The operating cost data not only indicated that there are definite economies of scale to be realized in the disposal phase of the total system but also that the costs of operating the collection system are influenced by the size of the area being served and population density. These conclusions are consistent with the findings of Schreiner, Muncrief, and Davis.

When viewing the estimated operating costs for each of the individual counties, it can be seen that as the average size of the landfill is decreased (an increased number of landfills for a given volume of waste) and the average size of the collection area is decreased, both disposal and collection costs increase. These increases indicate inefficiencies if more than one landfill is established in each county. The absolute and relative increases in collection costs as the number of landfills is increased is lowest for Lauderdale County, the most urban and densely populated.

When the three subregional multicounty combinations are considered, increased costs from decreasing the size of landfill operations is still apparent, but the costs of collection tend to decrease as the number of landfills is increased. For the Colbert County and Lauderdale County combination, there is little change in the annual collection cost as the number of disposal systems is changed. This again indicates the influence of population density on transportation costs. The more sparsely distributed population of the counties included in the other two combinations causes increased travel cost as the service area of each landfill is increased.

Table 2. Initial Investment and Annual Operating Costs for Specified Numbers of Landfills

Counties Served	Number of Landfills	Initial Investment	Annual Operating Costs Collection	Disposal	Total

[d] All five counties.

Economies of size appear to be evident in both phases of the total system when all five counties were considered as a single region. The cost savings of a relatively large collection system in the more densely populated counties appear to compensate for the increased costs of the large system in the more rural counties. These cost relationships are illustrated in figure 1. It is interesting to note that the regional operation with two landfills gives the minimum annual operating cost for both collection and disposal.

The investment-cost data for the alternatives presented in table 2 would be valuable to the decisionmaker in deciding how much initial capital he would need to get the system going. The increases in these data are fairly consistent with the changes in total operating costs for each respective system. Because of this and the inclusion of interest and annual depreciation for capital items in the operating cost budgets, the total operating-cost figure should be used for selecting the least cost system.

The major objective of the research was to determine the least cost collection and disposal system for the total five-county area. The data presented in table 3 represent the total annual operating costs for various systems that serve the entire five-county region. These cost values indicate that definite dollar savings can be realized if the five counties considered in the study cooperate in the operation of a solid waste management system. This least cost system from the regional standpoint is to have two regional sanitary landfills. This alternative, with an estimated annual operating cost of $447,275, would per-

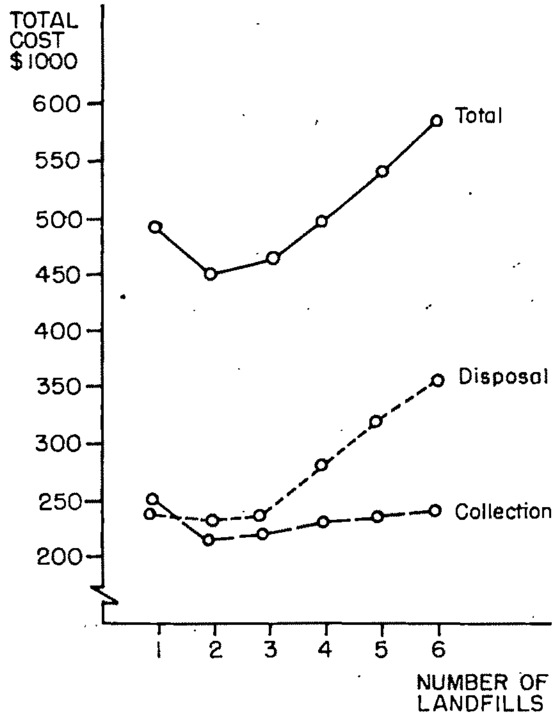

Figure 1. Annual operating cost for specified numbers of landfill operations in the five-county region

mit the counties to save more than $6,000 annually over the second best alternative and more than $72,000 over the alternative in which each provides its own system. In fact, there are at least ten possible systems that have a lower annual operating cost than the combined individual county system.

Summary

The concept of regional cooperation for the provision of necessary community services is presently receiving emphasis. The major justification normally given for such cooperative efforts is that the cost of providing the service might be reduced and better services be provided. Cost savings could be realized through less duplication of large and expensive equipment and by the regional system being large enough to operate with maximum economic efficiency.

The results of the study presented in this paper verify that there are definitely economies of scale to be realized in the disposal phase of a solid waste management system and that costs of collection are dependent on population density and the size of the service area. The combined collection and disposal costs indicated that a regional system can be justified for the selected study area. The least cost system for the five-county study area is to have two regional landfills. The annual costs associated with this system, $447,275, are substantially less than the $519,815 estimated for the system with each county operating independently. Nine other regional and subregional systems have lower annual operating costs than the combined individual county system, emphasizing the possibility for cost savings through cooperation.

Pests as a Common Property Resource: A Case Study of Alfalfa Weevil Control

Uri Regev, Andrew P. Gutierrez, and Gershon Feder

The biological interactions of a pest-plant system are incorporated into an optimal pest-control model, using data and estimated parameters specific to the alfalfa weevil. Due to the externalities inherent in situations involving common property resources, different solutions are obtained for private and societal formulations of the optimization problem. In contrast to current pesticide-spraying practices, it is shown that pesticide should be applied early in the season, before any damage can be observed.

Key words: aestivation, alfalfa weevil, common property resource, pesticide.

Recently, problems in pest management have attracted considerable attention in economic literature. Entomologists have concentrated on understanding the biological characteristics of the pest-crop relationships.[1] Economists have long recognized pest populations as detrimental common property resources. (Detailed definitions of common property resources and a development of the economics of common property resources are found in Brown; Cummings; Gordon; Plourde; Quirk and Smith.) Many have focused their attention on some of the economic aspects relating to economic thresholds (Headley; Hall and Norgaard), pest resistance (Taylor and Headley, Hueth and Regev), and pest-predator relationships (Feder and Regev). Others have used various optimization methods to solve single-season pest management problems (Shoemaker 1973a, 1973b; Talpaz and Borosh).

This paper describes an economic optimization model that incorporates detailed biological input specific to the alfalfa weevil. Using the available biological data and estimates, the problem is examined from a societal point of view and recognizes specific common property characteristics of the pest. The analysis points out the gap between private and societal control policies, offers estimates of shadow prices, and indicates a direction toward optimal pest-control policy.

Many features of pest-control problems lead to divergence between the optimal policy of a single decisionmaker and the society as a whole. The major types of externalities involved in pest-control problems include interseasonal dynamics, biological relationships with other pests and predators, environmental contamination by pesticide residues, resistance to chemical pesticides, effects of control on neighboring fields, and health problems relating to pesticides.[2] In this paper, attention is focused on only one of these aspects—stock externalities (Smith). These externalities, which are common among highly mobile pests, result from the dependence of population dynamics of the pest between seasons on the total population level in the region. During the season the farmer can control only the pest population in his field, which is, presumably, a small fraction of the total.[3] From an intersea-

[1] A survey of this literature is beyond the scope of this paper. Most of this literature is pest specific where an attempt is made to understand and model a given species. References on the biology of the Egyptian alfalfa weevil [*Hypera brunneipennis (boh.)*] can be found in Gutierrez et al.

[2] The extent of some of these externalities depends on the degree of pest mobility between fields.

[3] Intraseasonal pest migration between fields is negligible.

sonal point of view, the pest is a nonappropriable resource leading to a gap between marginal private and social benefits.

The Biological Model

A biological model for the relationships between the pest and the plant and the mortality effects of pesticide application on the pest is developed in this section. While the formulation is made specifically for the alfalfa weevil, the major pest for alfalfa in California, it can be generalized and adopted for many other pest problems as well. For a detailed description of the life cycle of the Egyptian alfalfa weevil, see Gutierrez et al.

Biological Background

Alfalfa is a woody perennial and is grown for hay and/or seed. The alfalfa stand grows for three to five years, at which time it has to be replaced because it has been invaded by weed species. The crop normally goes through two phases: a winter dormant period and a vegetative phase between harvest dates.[4]

Alfalfa regrowth during the spring begins when night temperatures are consistently above its thermal threshold (42° F.) and severe ground frosts have ceased. The rate of growth of alfalfa (i.e., dry matter production) is regulated by physiological time, measured in degree days and denoted by D° (Campbell et al., Wang). Alfalfa grows approximately 1,000D° between harvest dates.[5]

The alfalfa weevil has one generation per year. The adult spends the hot summer in sheltered places usually out of the alfalfa fields. It emerges to feed and lay eggs during the autumn after night temperatures of less than 42° F. occur (Gutierrez et al.). The population of adults migrates into the field at a rate that is a linear function of D°, reaching a maximum at about 180D°. The adult weevils mature, and females begin laying eggs after approximately 400D° and continue laying them until their death. A single larva hatches from each egg and begins to consume leaves at a rate that increases approximately in a geometric pattern over D°. Since larvae cannot survive a frost, all larvae that hatch before the last frost die prematurely and are not considered here. After 360D° of feeding, the larva is transformed into a nonfeeding pupa and, after a period, reaches the adult stage. The adult emerging from the pupa feeds for a while and then aestivates (summer hibernation), ending the year-long cycle. Adult feeding (both newly hatched and overwintering adults) is relatively minor and will be ignored in this study.

In the following, the behavior of the three major components of the system (the adult pest, the larva, and the plant), their interrelationships, and how they are affected by pesticide application are formulated. The specific algebraic forms chosen in this application, together with estimates of many of the parameters, rely heavily on a simulation model for the alfalfa weevil developed by Gutierrez et al. A detailed explanation of the parameters and data sources is given in the appendix.

The Time Dimension

As the developmental process of both the plant and the pest strongly depends on temperatures above certain thresholds (42° F. and 44.7° F., respectively), the physiological time scale of the plant has been used for both rather than calendar time. The time unit t is defined by a fixed interval, 60D°.

The choice of the initial time period, t_0, is related to the last frost and is based on the fact that frost suppresses the plant and kills the larvae, but not the adults. No damage is done by larvae prior to the last frost because the regrowth of the crop begins at the same time. Thus, t_0 is chosen at 240D° (four time intervals) before the last frost, which is the time interval from egg oviposition to hatching of the larvae because any larvae appearing before the last frost will not survive. The growth of the plant resumes following the last frost ($t = 4$).

In the single-season decision problem, the horizon, t_f, is chosen as the (physiological) time of the first alfalfa cropping. This is based on the observation that damage from the alfalfa weevil is negligible after that time.[6]

The Adult Stage

The dynamics of the adult weevil in the absence of control are presented in figure 1.

[4] When the alfalfa is grown for seeds, there is an additional phase. This paper deals primarily with alfalfa grown for hay.

[5] In the summer 1,000D° is approximately one month, and in the late winter and spring 1,000D° is approximately 3½ months.

[6] Although earlier cropping could be used as a pest control means (t_f becoming a decision variable), this possibility is not pursued here since the primary focus is on chemical control only.

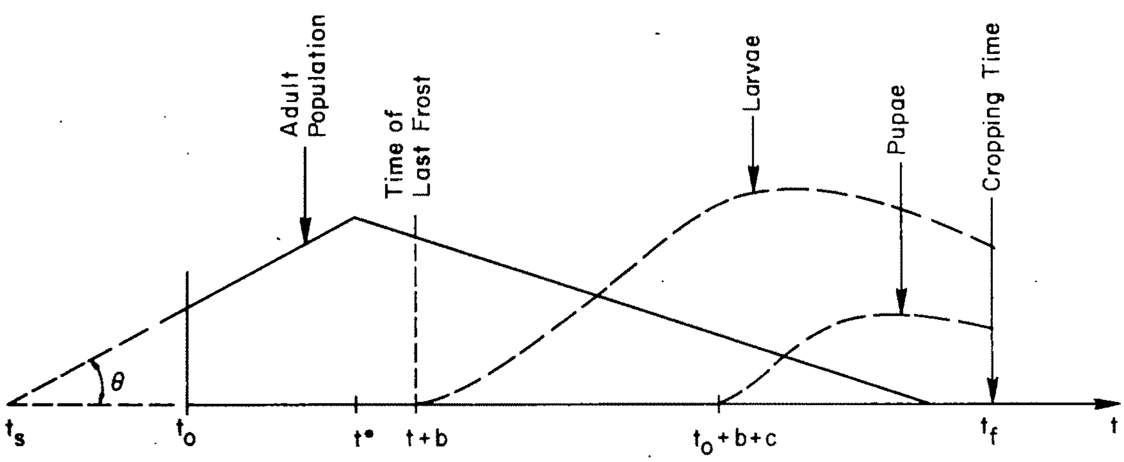

Figure 1. Time phenology of egyptian alfalfa weevil

The effect of pesticide application on the pest population is estimated by a dosage response curve (kill function). Using field data from Cothran and Christiansen, it has been estimated by the form $k = 1 - e^{-\alpha x}$, where k is the percentage of pests killed and x is the amount of pesticide (Hueth). Larvae have a higher susceptibility rate than adults.

The dynamics of the adult pest is then given by

$$
(1) \quad y_{t+1} = \begin{cases} y_t e^{-\alpha x_t} + \theta & t_0 \leq t \leq t^* - 1 \\ y_t e^{-\alpha x_t}\left(1 - \dfrac{1}{t^+ - t}\right), & \\ & t^* \leq t \leq t^+ - 1 \leq t_f \end{cases}
$$

$$y_{t_0} = (t_0 - t_s)\,\theta,$$

where y_t = number of adult pests per square foot at the beginning of the tth time period before spray, x_t, is applied, x_t = amount of pesticide applied (ounces per acre), θ = infestation rate (number of pests immigrating per square foot per time period), t_s = time of arrival of the first pest, t_o = initial time of the problem ($t_s < t_o$), t^* = time of peak adult population, t^+ = time of zero adult population, and t_f = time of cropping. Equation (1) reflects the effect of pesticide application on the natural adult pest level, which is presented in figure 1. The parameter θ (infestation rate) plays a crucial role in the problem, as it determines the severity of the potential pest damage.

Eggs, Larvae, and Pupae

The rate of oviposition, E_t, depends upon whether conditions and the age composition of the adult pests (see appendix). After time interval b, the eggs hatch, and the number of first-day larvae, L_t, in each time period is given by

$$(2) \quad L_t = y_{t-b}\, e^{-\alpha x_{t-b}}\, E_{t-b}$$

for $t_o + b \leq t \leq t_f$; otherwise, $L_t = 0$.

The number of larvae that become pupae, Z_t, at each time interval is the number of first-day larvae that survive all pesticide applications throughout their lifetime:[7]

$$(3) \quad Z_t = L_{t-c}\, e^{-\delta \Sigma x_\tau}$$

for $t_o + b + c \leq t \leq t_f$; otherwise, $Z_t = 0$, where δ = susceptibility parameter for larvae, c = length of larval life, and Σx_τ = total insecticides applied in time period $t - c + 1, \ldots, t$, which spans the lifetime of larva that becomes a pupa at time t.

Leaf Mass Consumed by Larvae

Consumption of leaf mass by a single larva is estimated by a geometric function of its age, and total consumption of leaf mass by all larvae (v_{t+1}) in period $t + 1$ is given by

$$
\begin{aligned}
(4) \quad v_{t+1} &= v_t\,(1 + a)\, e^{-\delta x_t} + \rho\, L_t \\
&\quad - Z_t\, \rho\,(1 + a)^c \\
&\text{for } t_0 + b - 1 \leq t \leq t_f - 1, \\
v_{t_0+b-1} &= 0,
\end{aligned}
$$

[7] Equations (1) through (4) slightly overestimate the population levels (after the adult peak), since natural mortality within the period is not considered. This, however, is not expected to cause a significant error. Equation (4) is a good approximation in the economically relevant region where $x_t > 0$ for some t. If $x_t = 0$ for all t, then the number of pupae is greatly reduced by internal competition; however, in that case the crop is completely destroyed.

where a = rate of increase in leaf consumption by the larvae and ρ = leaf mass consumption by a first-day larva during one time interval. The first term on the right-hand side of equation (4) represents the consumption of larvae that survived from the preceding time period. However, this term also includes consumption by larvae that had, in fact, become pupae. Therefore, their share is subtracted (the last term). The second term is the consumption by larvae that hatch in the tth time interval.

The Plant

Two components of the plant are considered—the stem and the leaves.[8] The leaf mass, m_t, measured in grams, grows as a function of both leaf mass and root reserves. The algorithm presented by Gutierrez et al. was too complex to utilize; hence, the following form is used:

$$(5)\quad m_{t+1} = m_t\,(1 + \eta_1) + \eta_2 - v_t; \quad t_o + b \le t \le t_f - 1;$$

m_{t_o+b} is given. This captures the essence of the simulation model. The plant grows from current photo-synthetic production, which is a feedback function, $m_t(1 + \eta_1)$, and from root reserves, η_2, which in reality fluctuate with time (i.e., if the plant is completely defoliated, $m_t = 0$, and it can regenerate by η_2). The stem mass is not directly damaged by the pest to any great extent but is indirectly affected by the leaf damage.

Using field data by Christiansen and Gutierrez, it has been possible to estimate the stem mass, S, at time t_f as a positively related function of the leaf mass in that time, $S = h(M)$, where $M = m_{t_f}$ is the leaf mass at cropping time.

Interseasonal Pest Dynamics

The infestation rate, θ, is a parameter that is determined by the following factors: total number of pests that aestivated from all the fields in the region, weather and ecological conditions during aestivation time, and the location of the field.[9]

Since pesticide applications do not appear to affect the pupae, the number of young adults per acre, A, that leave a given field can be approximated by $A = 43{,}560 \sum_t Z_t$.[10] Assuming that there are J acres in the region, then for a given acre i at a given season n, the infestation parameter, $\theta_{i,n}$, is given by the function

$$(6)\qquad \theta_{i,n+1} = g^*_i\left(\sum_{j=1}^{J} A_{j,n}\right),$$

where $A_{j,n}$ is the total number of adults that leave the jth acre for aestivation during the nth season.

The Economic Problem

The economic problem is to find the pest control policy that will maximize net gains. In the following analysis, a distinction is made between gains collected by each decisionmaker separately and those considered from the societal viewpoint.

The Private Viewpoint

The crop of alfalfa hay is measured by the weight of stems and leaves. However, its price is not fixed (even to the competitive farmer) and positively depends on the quality of the hay. A measure of the quality is the leaf-stem ratio. Let $p_m(M)$ denote the price of the hay; then

$$(7)\quad p_m \equiv g\left(\frac{M}{S}\right) \equiv g\left(\frac{M}{h(M)}\right) \equiv p_m(M),$$

where S is stem weight at cropping time and $h(M)$ is a function relating stems to leaves $[h'(M) > 0]$.[11] It is further assumed that p_m is continuous with $0 \le [p'_m(M) = g'(\cdot)\ (h -$

[8] The horizon is one season (until the first cutting of the hay). The effect of leaf damage on root reserve depletion was considered originally since this factor may affect second and third croppings. However, observations in commercial fields show a negligible effect of the pest either within the horizon or on the subsequent croppings and no effect later on.

[9] A region is defined here as the area comprising all fields such that an aestivating pest from one field could possibly reach any other field in the region during the following season. Although the weevil has a tendency to aggregate during the aestivation period, it is believed to be highly mobile during the phases of migration to and from the fields. Experience with other insects of the same biological order suggests that the weevil may cover considerable distances at the time of migration. It is thus very likely that weevils originating from any one field will eventually arrive at other fields in the region. One should recall that most alfalfa growing farms in California are less than 200 acres in size, which is considered well within the migration range of the weevil.

[10] Since biological data were given per square foot and economic functions are on a per acre basis, the conversion factor (43,560) was used when necessary.

[11] Prime denotes first derivative, and double prime denotes second derivative. When functions of two or more variables are defined, their partial derivative will be denoted by subscripts of the variable with respect to which derivative is taken.

$h'm)/h^2] < \infty$, namely, that the price is nonnegatively related to leaf mass, M. The revenue of a single farmer is thus

$$(8) \qquad R(M) = p_m(M)[M + h(M)],$$

and, under the above assumptions, $R'(M) \geq 0$. The sign of $R''(M)$ depends on the signs and magnitudes of $g''(M)$ and $h''(M)$; but if both equal 0, then $R''(M) \geq 0$.

The farmers are assumed to be pricetakers in the pesticide market, and a one-season objective function is

$$(9) \qquad \Pi^{(1)} = R(M) - p_x \sum_{t_0}^{t_f} x_t,$$

where p_x is the fixed pesticide price.[12] The first problem is a single-season decision: maximize equation (9) subject to the equations (1), (4), (5), and (8) and the constraint that all variables in the system be nonnegative. It is assumed that no single farmer is large enough to affect the regional pest dynamics significantly and therefore would not take it into consideration in his pest control policy.

The objective defined by equation (9) fails to consider the possibility that secondary pests are likely to develop following pesticide applications because of the disturbed ecological relationships in the field. In alfalfa, it has been observed that, when pesticides are applied late in the season against the major pest—the weevil, secondary pest outbreaks may occur, requiring the use of additional control measures in subsequent time periods of the season (Summers and Cothran 1972a). As the secondary outbreaks occur beyond the specific horizon adopted in this model, they are taken into account by a set of extra charges on pesticide applications that occur at later time periods within the model's horizon. The penalties reflect the cost of additional controls that will result later from the current use of pesticides. Alternatively, these charges may be considered as a reflection of yield reduction in later croppings in the season resulting from secondary pest outbreaks. The objective function is then

$$(10) \quad \Pi^{(2)}(x, \theta) = R(M) - \sum_t (p_x + \mu_t)x_t,$$

where μ_t is the appropriate charge that accounts for the damage of the secondary pest. A discussion of μ_t is presented in the appendix.

The Societal Viewpoint

The objective function defined by equation (10) overlooks several major aspects of the pest-control problem. Among them are the aspects of pest resistance, interseasonal pest dynamics, and a few types of external effects of pesticide applications on the environment. The present model, however, focuses only on the interseasonal relationships and assumes that no other external effects exist.

Assuming pests are identically distributed over the region, a central decision agency would maximize the present value of the net returns per acre:

$$(11) \qquad \Pi^{(3)} = \max_{\{x_n\}} \sum_{n=0}^{N} \beta^n \, \Pi^{(2)}(x_n, \theta_n),$$

where x_n = vector $(x_{1n}, x_{2n}, \ldots, x_{tn}, \ldots, x_{t_f n})$ of controls at the nth season, $\beta^n = 1/(1 + r)^n$ = discount factor using the appropriate discount rate, r, and N = planning horizon. This maximization is subject to the same constraints as before, equations (1), (4), (5), and (8), repeated for each season. An additional set of constraints accounts for the interseasonal relationship

$$(12) \quad \theta_{n+1} = g^*\left(\sum_j^J A_{jn}\right) = g^*(JA_n) = g(A_n) = \gamma \cdot A(x_n, \theta_n); \quad n = 0, 1, \ldots, N,$$

where A_n is the number of adult pests leaving for aestivation per acre during the nth season, γ is the parameter of proportion between adults leaving per acre at the nth season and the rate of infestation in season $n + 1$, and the initial infestation rate, θ_0, is a given parameter. This equation is similar to equation (6) but is simplified due to the assumption of identical pest distribution and the linearity of the function $g(\cdot)$.

Private Vis-à-Vis Societal Policies

Private decision rules are obtained by a maximization of the problem for one season. Define $G(x, \theta)$ as the Lagrangian corresponding to $\Pi^{(2)}(x, \theta)$ and the constraints (1), (4), (5), and (8). The private decision rules obtained by the maximization of $G(\cdot)$ are

[12] This objective function ignores the possibility of fixed application costs, which will be discussed later when the computational results are analyzed.

(13) $$G_x(x, \theta) = 0.$$

Societal decision rules are obtained by

(14) $$\max_{\{x_n\}} \sum_{n=0}^{N} \beta^n \{G(x_n, \theta_n) - \beta\lambda_{n+1}[\gamma A(x_n, \theta_n) - \theta_{n+1}]\},$$

where λ_{n+1} is the Lagrangian multiplier associated with the constraint (12).

Burt and Cummings describe a general optimization model for natural resource management. Necessary conditions for a solution to this problem include

(15) $$G_{x_n} - \lambda_{n+1}\beta\gamma A_{x_n} = 0, \quad n = 0, 1, \ldots, N,$$

and

(16) $$\lambda_n - \lambda_{n+1}\beta\gamma A_{\theta_n} = -G_{\theta_n}, \quad n = 0, 1, \ldots, N.$$

The expression $\lambda_{n+1}\ \beta\gamma\ A_{x_n}$ reflects the future gains (by reducing θ) of a marginal increase in the control at the nth period; it is appropriate to denote it as a (negative) "user cost" (Scott).

If a solution to equation (14) were possible, λ_n could be found, and a path of optimal shadow prices over time would yield the optimal policy. The curse of dimensionality, however, impedes such a solution.[13] One approach adopted here is to derive the societal steady-state solution by means of solving iteratively a sequence of one-season problems.

At the steady state, if it exists, for sufficiently large n, $\theta_n = \theta_{n+1} = \theta$, and $\lambda_n = \lambda_{n+1} = \lambda$. For this case, equations (15) and (16) become

(17) $$G_x - \lambda\beta\gamma A_x = 0,$$

and since $A_\theta = 1/\gamma$,

(18) $$-G_\theta = (1 - \beta)\lambda.$$

In the following, it is shown how the steady-state infestation rate, θ, and its corresponding shadow price, λ^*, could be found and the implications for pest-control policies analyzed. Define a modified one-season problem,

(19) $$\max \mathscr{L} = G(x, \theta) - P \cdot A(x, \theta),$$

where P is now an arbitrary parameter. The necessary condition is

(20) $$G_x - PA_x = 0.$$

Comparison of equations (17) and (20) indicates that, if one could find a value of P such that $P = \lambda^*\beta\gamma$, this would represent at steady state the marginal cost to society of pests leaving for aestivation and, therefore, yield the optimal steady-state solution. The procedure is as follows. Equation (19) is solved for some arbitrary P and a given θ_0. Using equation (12), θ_1 is obtained and the solution procedure is carried out iteratively. For any arbitrary P, the solution for the modified problem, equation (19), yields a value for $\mathscr{L}_\theta = G_\theta - PA_\theta$. In the above iterative procedure, $\{\theta_n\}$ converges to a steady state $\theta^*(P)$; insert $P = \gamma\lambda\beta$ and use equation (18). Then

(21) $$P = -\beta\gamma\mathscr{L}_\theta = -\frac{\gamma\mathscr{L}_\theta}{1 + r}.$$

This equation gives the optimal steady-state value, P^*, as a function of the discount rate, r.

Analysis of Results

The results presented here for the pest-control policies in alfalfa are based on the data and estimation procedures explained in the appendix. The analysis of the results focuses on the comparison of optimal pest-control policies obtained from private and societal decision rules and currently used practices. The solutions have been obtained by a nonlinear programming computer program written by Abadie (Generalized Reduced Gradient Algorithm), which was executed on a CDC 6400 computer (Abadie and Guigou).

Solution for a Single Decisionmaker

A single farmer is concerned only with pest control within a single season. He should, however, be aware of outbreaks of secondary pests and consider them in his decisions. Therefore, the problem of maximizing $\Pi^{(2)}$ (equation (10)) is regarded as the relevant problem for the single farmer.

Application of a total of twenty-eight ounces per acre of the pesticides is optimal in this case where applications are made in time

[13] The complexity of the biological relations has been greatly simplified in the current model, but the size of a single-season problem for the case study actually solved could not be reduced below 50 variables and 40 constraints, with most of the constraints nonlinear.

Table 1. Current and Optimal Private Pesticide Application

Type of Solution	Application Time (60 D°) 1	2	3	4	5	6	7	8	9–21	Total Amount Applied	Net Pest Control Revenue Per Acre
	(Oz./Acre)										
Current practices	0	0	0	0	0	0	0	16–32	0	16–32	\$88–\$101
Unrestricted private optimal solutions	1.5	9.8	4.3	12.6	0	0	0	0	0	28.2	\$116.84

periods 1 through 4 only (table 1). The optimal timing of pest-control applications is in time periods up to and including the time of peak adult population (cf. figure 1). This is prior to the last frost, at which time the seasonal regrowth of the alfalfa starts. Furthermore, since the frosts destroy the larvae, pesticide applications prior to the last frost are directed primarily against the adult pest. This result is strengthened by the fact that pesticides are more efficient in the control of larvae than of the adult pest (e.g., given the parameters estimated here for pesticide application of sixteen ounces, about 20% of the adults compared with 4% of the larvae will survive; see appendix). Pesticide applications made early in the season reduce not only adult numbers but also the future population of eggs and larvae. The common practice at present is to apply pesticide only when large larvae are found in the field, which is approximately three time periods after the last frost. The amount of pesticide applied varies greatly in practice, ranging from less than sixteen ounces to thirty-two ounces per acre depending upon the timing of the first application and on the actual damage throughout the season. Comparison of the net pest-control gains of private optimal policy with current practices (table 1) clearly indicates the advantage of the former. The most important practical conclusion of these results is, however, the indicated shift in the timing of pesticide applications to a new control target (i.e., the adult pest rather than the larvae).

The results presented above are based on the model assumptions that include time-dependent charges on applications. These charges impose heavier costs on applications that occur later in the season. Compared with the basic pesticide cost of forty cents per ounce, the charges actually used to obtain the above results are zero up to (and including) the fifth time period but increase linearly thereafter, reaching \$1 per ounce in the tenth period and remaining constant at that level (see explanation in the appendix). Since the timing of applications is a major point of difference between the results obtained here and current practices, it is interesting to examine the sensitivity of the control policy to the extra charges, μ_t, imposed on pesticides. The solution to the problem with all extra charges set at the zero level is found to be identical with the solution of the problem incorporating the charges. It is thus concluded that, even without consideration of secondary outbreaks, spraying should take place before the last frost and be directed against the adult pest.

This last result is not changed when the effects of fixed application cost are considered. Since fixed costs could not be directly treated in our computer program, an indirect approach was used. Solutions were obtained to the problem under constraints imposing one or two treatments in specific time periods. Comparing the values of the objective function, it was observed that one treatment in the third period or two treatments in the second and fourth periods were superior to all other single or double treatments, respectively (table 2). The difference between the best two-treatment and one-treatment objective functions is \$2.70 per acre. Thus, if the fixed application cost is more than \$2.70, then a single treatment (in the third period) is preferred. The unrestricted solution calls for four treatments; however, its objective function is only ten cents per acre higher than the two-treatment solution. In any case, treatments are suggested early in the season only.[14]

Aspects of a Societal Solution

The previous results took no account of the future potential damage embodied in pests that currently leave for aestivation. As noted be-

[14] Not all possible 190 combinations of two treatments were calculated, since the pattern of results allowed us to discard most of the combinations a priori.

Table 2. Policies for Spraying When Application is Imposed in Specific Periods

Periods of Application	Value of Objective Function ($)	Amount of Pesticide in Respective Periods (oz./acre)
One treatment		
1	109.6	23.0
2	112.8	24.0
3	113.9	24.4
4	113.5	24.2
5	110.5	23.3
6	102.8	17.9
7	97.6	13.6
8	94.5	10.3
Two-treatment combination		
1–3	114.8	8.2–18.1
1–4	116.1	11.6–16.9
1–5	114.9	13.9–15.0
1–7	109.6	22.6– 0.5
2–4	116.7	13.4–14.6
2–6	113.7	20.6– 5.5
3–4	115.7	13.8–12.6
3–6	114.0	23.1–16.5
4–8	114.3	22.9– 2.7

Note: These results are for the individual farmer problem and assume that no spraying occurs in all other time periods.

fore, the sequence of shadow prices and the optimal policy cannot be practically calculated. One way to account for the dynamic effects is to impose various values for the shadow price, λ, and to study the sensitivity of the solutions. Another approach used here is to calculate the optimal solution at steady state by iterative procedures.

For the first method three alternative values for P are used, and the results are presented in table 3. As in the solution for a single farmer's problem, for all shadow prices, the bulk of the spraying takes place early in the season prior to the last frost. However, larger values of P imply that both a greater total dosage and an additional application in the eighth period are required, even though the latter application is relatively small. From an examination of the suggested amount of pesticides applied (using different values of P), it appears that P = 0.23¢ per 1,000 pests is a reasonable upper limit for P and, if this is the case, no pesticides should be applied after the fourth period.

Using the results in table 3 as an indication of the effects of various values of shadow prices is one way to examine the effect of fixed application costs on spraying policy. The procedure used is similar to the one employed when fixed application costs were introduced for the single farmer's problem. In this case only a few relevant combinations were checked (P = 0.23¢ and P = 2.3¢ per 1,000 pests). Table 4 brings together those results but only for the time combinations that yielded the highest values of the objective function. For P = 2.3¢ the eighth period application should be eliminated if the fixed application cost is more than $2.75. The amount of pesticides is essen-

Table 3. Sensitivity of Solutions to Arbitrary Shadow Prices Imposed on the Modified One-Season Problem

	Solution 1	Solution 2	Solution 3	Solution 4
P (¢/1,000 pests)	0	0.23	2.3	9.2
Objective function ($/acre)	116.84	113.01	100.79	90.20

[a] $P = 2.3$ ¢/1,000 pests.
[b] $P = 0.23$.

tially not affected by fixed cost (for both prices), and the same timing of application is generally retained.

Comparing the societal with the private solution, it is concluded that the inclusion of future damage results in heavier spraying and smaller numbers of pests leaving for aestivation. This conclusion is maintained with or without fixed application costs. As will be demonstrated below, pesticide use at steady state is only slightly higher than the solution suggested by the last row in table 1 (private solution) but is much lower than the one suggested by tables 3 and 4. This may suggest that, along the unknown optimal path for the societal solution, pesticide use should be high initially and then decline as it approaches the steady state. It should be noted that this policy would be the optimal one only if resistance to pesticides is absent and is not expected to develop. The problem may be further complicated by the recognition of other externalities.

The steady-state solution is based on successive iterative solutions of the modified one-season problem, and the optimal steady-state shadow price is obtained as a function of the interest rate. The procedure is based on the results obtained in equation (21) in the following way. For some (arbitrarily fixed) value of γP (using $\gamma = 0.0038$), the problem defined by equation (19) is solved iteratively, where in each iteration θ_{n+1} is determined by the value of A_n using equation (12). $|\theta_{n+1} - \theta_n| < \epsilon$ has been used as the criterion for terminating the iterative process and determining $\theta^*(P)$ in the steady-state value. In the computation, $\epsilon = .01\theta_n$ has been used. Equation (21) is then used to determine the discount rate r for which the above values of P and $\theta^*(P)$ would be optimal. The results form a mapping from r into $[P, \theta^*(P)]$ (figure 2). $P(r)$ is negatively sloped function that goes to 0 as r goes to ∞ and reaches a finite value when $r = 0$. This mapping gives a target for pest-control policy in the sense that, given a discount rate of, say, 9%, an optimal societal steady-state rate of infestation should be about 0.02, and the corresponding shadow price P is 2.3¢ per 1,000 pests. It is important to note that, once a steady state $\theta^*(r)$ is obtained, the level of pesticide application is about the same for all values of P that have been tried—around thirty-two ounces per acre—compared with the private optimum of twenty-eight ounces per acre. The timing for pesticide applications is, however, similar to the solution for the former (private) problem. Unlike the results in table 3, the eighth period application is eliminated in the steady-state solution. The impact of fixed application costs is as before; it reduces the number of applications without changing the general timing of the applications and their total amount.[15]

[15] In order to save space, these results are not presented.

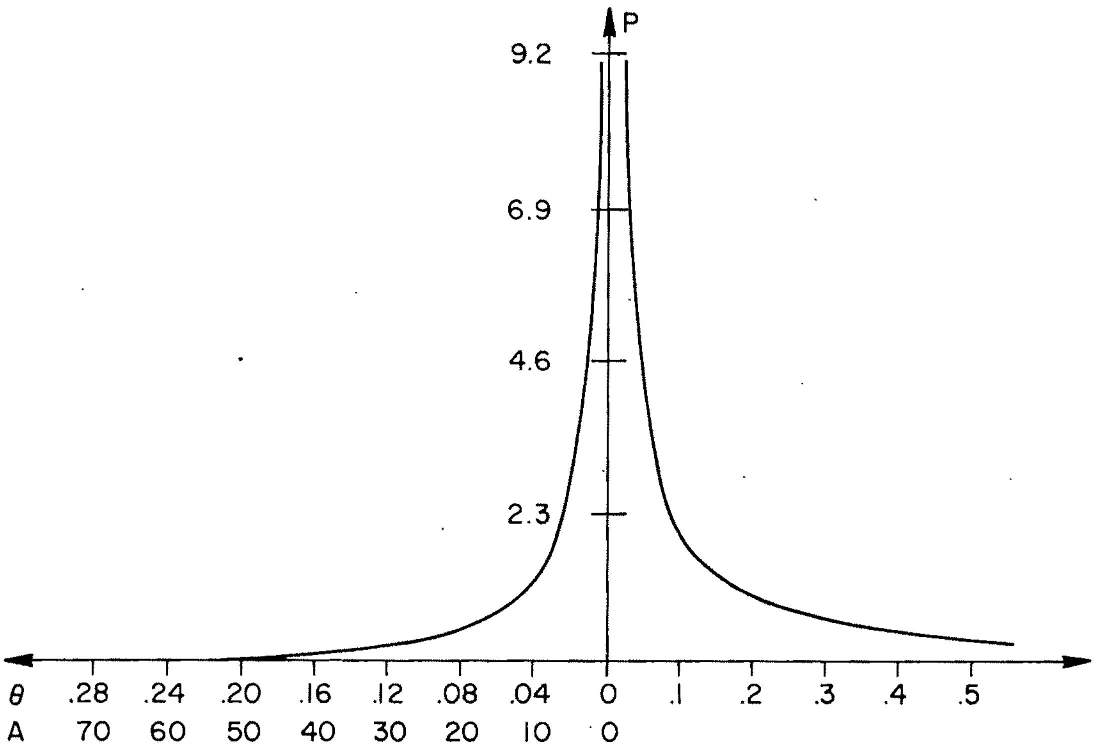

Figure 2. Optimal steady-state relationships between discount rate, *r*, penalty on pests leaving the field, *P*, in cents per 1,000 pests, and the number of pests, *A*, leaving the field (infestation rate, *θ*, is a fixed proportion of the number of pests leaving the field)

Conclusion, Policy Implications and Extensions

The following points summarize the major results and offer some suggestions for future research. The major discrepancy between the results obtained here and current practices involves the timing of pesticide application. The results obtained here indicate the advantage in applying pesticide prior to the growth season. Specifically, application is centered around the time period in which the number of adult pests peaches its peak. Within a given season, the individual farmer is not affected by his neighbors' decisions; however, in the long run each farmer is affected by the cumulative effects of the individual decisions. In this case the pest constitutes a "common property resource," and a nonregulated market would not yield the optimal solution. The optimal societal solution could be implemented by an information agency that would enhance mutual cooperation between farmers (e.g., the Extension Service). It has been shown that a shadow price of 2.3¢ per 1,000 adults emerging per acre is the steady-state social cost. This corresponds to a discount rate of approximately 9%. Higher discount rates imply lower social cost and higher steady-state infestation rates.

Future research is clearly desirable to ascertain many of the functions and to obtain better estimates for some of the parameters before this solution is to be applied. These results are, therefore, important in indicating the direction for better pest-control policies and in pointing out directions for future research regarding critical parameters and functional relations upon which the solution rests. Further work is also needed to obtain the optimal policy path over time. This model can be extended by using the interseasonal results obtained here in a dynamic programming framework to find a multiseasonal optimal policy. One important component that has not been incorporated in this model is pest resistance to chemical pesticides. However, this possibility raises the question whether a policy that leads to heavy suppression of the pest by chemical pesticides is desirable, as it may bring on a speedy development of resistance.

Appendix

Data Sources and Estimation Procedures

The appendix presents the data sources, estimation, and derivation procedures of the various parameters in the model as applied to the control of the Egyptian alfalfa weevil in California.

The Rate of Infestation, θ

For a one-season problem, the pest infestation rate θ is a constant. This has been estimated at 0.174 by Gutierrez et al. from early season field counts. The interseasonal relationship $\theta_n = \gamma A_{n-1}$ is an approximation adopted here. The estimate of γ (0.0038) is based on the observation that, using current practices, the average adult peak is about 0.05 of the number of adults that leave the field, and adult peak time occurs thirteen time periods after the arrival of the first adults from aestivation.

The Kill Function

The kill function is taken from a field pesticide experiment by Cothran and Christiansen. Pesticides were applied against the adult population early in the season, and the effect measured the number of offspring produced by the survivors. This is a reasonable estimate of survivorship because the adults remain in a very limited area of the field, and the subsequent count of larvae accurately reflects their survivorship via fecundity when compared to an untreated control. The resultant survivorship curve was estimated from their field data by the curve e^{-ax} with

$\alpha = 0.1$ and is representative of the effects of Carbofuran and Heptachlor on adult Egyptian alfalfa weevil populations ($R^2 = 0.89$ and the student t-value was 16.7). Pesticide applications are more effective against larvae, and $\delta = 0.2$ (equations (4) and (5)) has been estimated from Summers and Cothran (1972b) by comparing equivalent application rates on estimated larval survivorship and assuming that the kill function has the same form.

Oviposition Rates, E_t

The maximum oviposition rate is 2.2 eggs per female per D° (= 132 eggs per one time interval). Laboratory feeding experiments and field observations indicate that the beetles fail to feed during periods of adverse weather conditions (i.e., too cold, rainy, etc.) and, as a result, fecundity declines. Gutierrez et al. describe these experiments and formulate equations to estimate weather effects on egg laying. These occur annually, although the pattern may vary. Hence, a pattern and magnitude of these effects for a typical year were estimated and included in the model. Fecundity is also age dependent and was estimated from laboratory experiments. Field and laboratory data indicate that adults entering the field must feed approximately 400 D° before they can oviposit. Incorporating all of these effects resulted in the following oviposition rates per adult: $\{E_t\} = \{1.8, 9.6, 14.2, 11.7, 19.2, 27.0, 33.3, 37.8, 42.5, 41.9, 55.8, 60.9, 66.0, 32.2\}$, for $t = 1, 2, \ldots, 14$.

Larval Consumption Rate

Koehler and Pimentel estimated leaf consumption rates for a related species of alfalfa weevil. Because the species are taxonomically close and of approximately the same size, it was felt that this was a reasonable value to use in the model. A geometric function was fitted to their data.

$$\rho \sum_{t=1}^{6} (1 + a)^{t-1} = 7.5,$$

where the total consumption of a larva during its lifetime (six periods) is 7.5 milligrams of leaf tissue, $1 + a$ (= 2.3) is the geometric rate of increase of the function per 60 D°, and ρ (= 0.0043 grams) is the consumption of a larva during its first 60 D°.

The Plant

The parameters η_1 and η_2 of equation (5) were estimated as follows. Using a simulation model of the plant, eight successive observations of m_t were obtained for the hypothetical situation of zero pest population (i.e., $V_t = 0$). As the simulation model's time period is approximately twice as long as the present model, the following equation was estimated:

$$m_{t+2} = (1 + \eta_1)^2 m_t + [2 + \eta_1]\,\eta_2.$$

This equation is easily derived from equation (5). The estimates were

$$(1 + \eta_1)^2 = \underset{(3.5)}{1.1256}$$

and

$$\eta_2\,[2 + \eta_1] = \underset{(16.1)}{1.0914},$$

where the figures in parentheses denote student t-values. The R^2 of the regression was 0.977. On the basis of these estimates, η_1 and η_2 were calculated. Total stem weight, S, (grams per square foot) is linearly related to the amount of leaf tissue at harvest, M, by the function $S = 9 + (15/16)\,M$, $0 \le M \le 16$, grams per square foot. All field estimates were estimated on a square foot basis, but economic values are scaled to dollars per acre.

Alfalfa Quality and Price

The quality of alfalfa hay can be measured by its leaf-to-stem ratio. The price P_m per gram of alfalfa is strongly influenced by this ratio. The price for alfalfa which has been used here is \$80 per ton for maximum quality and \$5 per ton if completely defoliated. By linear interpolation, $P_m = (0.55 + 0.516\,M)10^{-5}$ in dollars per gram. The revenue, R, is then $R = (S + M)\,P_m = 2.16 + 2.49\,M + 0.435\,M^2$ in dollars per acre.

Pesticide Cost

Pesticide costs (forty cents per ounce) are reasonable estimates for alfalfa production in northern California during the 1972–74 period and were obtained by consultation with W. R. Cothren and R. W. Bushing, University of California, Davis. This is the current cost estimate for Furdan, the most commonly used pesticide applied for the control of the Egyptian alfalfa weevil. Exact estimates for the cost of secondary pest outbreaks, μ_t, of aphids, lepidopterous, and other pests are unavailable and have been estimated from experience. It is commonly observed by entomologists that applications of pesticides on alfalfa (and other crops, e.g., cotton) to control pests result in additional pesticide use to control the induced secondary pests. Pesticides applied late in the spring disrupt the ecological relationships more than pesticides applied during the winter period when most of the nontarget species are dormant (Summers and Cothren 1972b). This is reflected as an increasing linear charge of 0 from the last frost (the fifth period) to a maximum of \$1 at the tenth period and thereafter; i.e., $\{\mu_5, \mu_6, \mu_7, \mu_8, \mu_9, \mu_{10}, \mu_{11}, \ldots\} = \{0, 0.20, 0.40, 0.60, 0.80, 1.00, 1.00, \ldots,\}$.

An Analysis of Alternative Financing Strategies and Equity Retirement Plans for Farm Supply Cooperatives

Wilmer A. Dahl and W. D. Dobson

Cooperatives are experiencing pressures to increase cash patronage refunds, reduce financing costs, and retire equity capital of farmer-members who die, retire, or leave the cooperative's service area. Farm supply cooperatives could increase cash patronage refunds by over 90 % and reduce financing costs by 6% to 9% by employing moderately different capital acquisition practices. Solvency of the cooperatives could be reduced substantially if mandatory equity retirement plans being considered by legislators and courts were adopted.

Key words: cooperatives, equity retirement, financing costs, linear programming, patronage refunds.

U.S. agricultural cooperatives rely heavily on revolving fund capital for financing growth and operations.[1] There are advantages to this financing practice. Problems with debt service and risk normally are small when this type of equity capital is the primary capital source. The revolving fund also provides a convenient way for cooperatives to raise capital. And, in theory, revolving fund financing keeps ownership of the cooperative in the hands of present members and financial contributions of members proportional to the use they make of the cooperative.

However, as the following studies indicate, this financing practice also has created problems. Griffin; Hulbert, Griffin, and Gardner; Fenwick; and Snider and Koller suggest that capital costs of agricultural cooperatives are higher than necessary because the firms use too much revolving fund (equity) capital and too little debt. Snider and Koller report that some cooperatives place a zero cost on revolving fund capital, which causes them to underestimate the overall cost of capital and overinvest in facilities.[2] Tubbs indicates that for aggressive farmers who look to expand their farm businesses capital contributions to cooperatives are frequently made at a large and often unrecognized sacrifice to the contributing farm firm (p. 6). Tubbs also shows that some farmers in higher income tax brackets actually lose money if they accept a cooperative's patronage refund when it consists of the 20% minimum in cash and an 80% book credit.[3] This occurs because the farmer-member pays income taxes on both the cash portion and book credit immediately and may not receive any cash payment for the 80% book credit for many years under the revolving plan. Therefore the farmer may find that the discounted present value of the cash pa-

Wilmer A. Dahl is an assistant professor of agricultural economics at Purdue University; W. D. Dobson is an associate professor of agricultural economics at the University of Wisconsin, Madison.

This article is based on a portion of Wilmer A. Dahl's Ph.D. thesis. Financial support for the research was obtained from Hatch Project No. 1975, University of Wisconsin, Madison, the University of Wisconsin Center for Cooperatives, and the Cooperative Foundation of St. Paul, Minnesota. Helpful comments on the manuscript by J. Schmidt and F. Groves of the Department of Agricultural Economics, University of Wisconsin, Madison; L. Schrader, Department of Agricultural Economics, Purdue University; and *Journal* reviewers are gratefully acknowledged.

[1] Revolving fund capital is obtained from capital deductions from members and/or margins realized from the cooperative's operations. Under a revolving plan, earnings or capital deductions obtained during the current year are used to retire the oldest outstanding revolving fund capital furnished to an association by farmer-members of earlier years.

[2] Snider and Koller found that certain Minnesota milk cooperatives underestimated their weighted average capital costs by over four percentage points when revolving fund capital was priced at a zero level. Results of this study showed that the average Wisconsin farm supply cooperative would underestimate its weighted average cost of capital by about two percentage points if a zero cost was attached to its revolving fund capital.

[3] The "20% minimum in cash" is a requirement of the Revenue Act of 1962. Under this Act, cooperatives must pay at least 20% of their member patronage refunds in cash if they wish to deduct total member patronage refunds from gross income when computing federal income tax obligations.

tronage refund and book credit is less than his immediate tax obligation on the total patronage refund.

Cook reports that many U.S. agricultural cooperatives have failed to develop systematic plans for retiring the equity capital of members who die, retire, or leave the community. Cooperative management is experiencing increasing pressure from members and legislators to develop such plans. According to Cook, bills have been introduced and/or court actions instituted in eleven states to require agricultural cooperatives to systematically retire equity capital of members who are no longer actively associated with the cooperative.

The criticisms contained in the above studies call for agricultural cooperatives to reduce financing costs, increase cash patronage refunds, lessen financial sacrifices of members, reduce the length of revolving periods, and retire equity capital of members who die, retire, or leave the cooperative's trade area. However, it is difficult to draw clear prescriptions from the studies. The studies fail to indicate, for example, what constitutes an optimal financial structure for agricultural cooperatives and whether cooperatives would realize substantial cost savings if they achieved optimal financial structures. Also, it is not clear whether it would be feasible for cooperatives to adopt financing practices that would reduce financing costs substantially and remedy other financial management problems identified in the studies.

Objectives of Study

This study examined the optimal financial structure and feasibility questions. Specific objectives of the study were the following: (*a*) to determine the optimal financial structure (i.e., least-cost combination of revolving fund capital, short- and long-term debt, common stock, preferred stock, etc.) for representative Wisconsin local farm supply cooperatives under nine different financing plans for 1966 through 1974; (*b*) to determine how much financing costs of the cooperatives would have been reduced if they had followed the prescriptions represented by the optimal structures (the different financing plans considered involve five- and ten-year revolving plans and cash patronage refunds of 20%, 40%, 60%, 80%, and 100% of total patronage refunds); (*c*) to examine liquidity and solvency of the cooperatives under each of the different financing plans to determine which of the plans would be most feasible to adopt; and (*d*) to examine solvency of the cooperatives under plans that require them to retire equity capital of members who die, retire, or leave the areas served by the cooperative.

This study was based on data for all 189 Wisconsin farm supply cooperatives. The cooperatives that provided the data serve a cross-section of dairy, beef, hog, and cash grain farmers. Therefore, the results may be applicable to farm supply cooperatives elsewhere in the United States.

Linear Programming Models Used in Study

Recursive linear programming (LP) models were employed in the study to determine optimal financial structures for the Wisconsin local farm supply cooperatives. The LP models used in the analyses are recursive in the sense that constraints for a given year depend upon the nature of the optimal solution for the previous year. In the study, base period figures for 1966 and figures from the optimal solutions for seven subsequent years were employed in the models to compute minimum cost financial structures for representative Wisconsin farm supply cooperatives for each year of the 1966–74 period.

Capital source variables included in the objective function of the models were as follows: C^{ps} (preferred stock), C^{cs} (common stock), C^{bct} (Bank for Cooperatives term loans), C^{bcs} (Bank for Cooperatives seasonal loans), C^{ci} (certificates of indebtedness), C^{ost} (other source term loans),[4] C^{oss} (other source seasonal loans), C^{as} (allocated savings or revolving fund capital), and C^{us} (unallocated savings). The minimum cost financial mix was selected by the LP models from the above source variables subject to the following constraints. Total short-term debt, long-term debt, plus equity capital acquired each year must equal capital needed each year. Term loans acquired from the Bank for Cooperatives and other sources must be repaid to lenders with interest in eight years; term loans acquired from commercial banks must be fully repaid with interest to lenders in ten years. Federal income taxes at appropriate normal and surtax

[4] Other source debt consists primarily of loans made to local cooperatives by affiliates of regional cooperatives.

rates must be paid on unallocated reserves of cooperatives. Preferred and common stock issued must not exceed amounts authorized in bylaws of cooperatives. Also, annual increases in sales of preferred stock, common stock, and certificates of indebtedness must not exceed upper bounds based on historical sales figures. Annual increases permitted under the models averaged 7.1%, 2.6%, and 14.2%, respectively, for common stock, preferred stock, and certificates of indebtedness. Net savings generated each year by a cooperative must be distributed to four accounts—stock dividends, unallocated savings (unallocated reserves), federal income taxes, and total patronage refund (TPR). Under the models, TPR was further subdivided into cash patronage refunds (CPR) and allocated savings (AS) or book credits. The allocated savings were revolved back to farmer-members at future dates under the revolving plans incorporated in the models.

Minimum cash patronage refunds expressed as a percentage of total patronage refund and length of revolving period incorporated into constraints were as specified in table 1 for the different models. The model designations appearing in table 1 serve as a key for identifying solutions in subsequent discussions. Thus, model II will refer to an LP solution in which a cooperative pays a 40% cash patronage refund under a five-year revolving plan.

Table 1. Cash Patronage Refunds and Length of Revolving Period for LP Models Employed in Study

Model	CPR as Percentage of TRP	Length of Revolving Period (years)
I	20	Not computed[a]
II	40	5
III	60	5
IV	80	5
V	100	5
VI	40	10
VII	60	10
VIII	80	10
IX	100	10

[a] Model I calculates least-cost financial structures under the restriction that allocated savings revolved back to members must equal averages of the actual amounts revolved back to members. Figures on the actual amount of capital revolved back to members were available from the financial statements of the cooperatives. But, typically, it was impossible to determine from these financial statements what length of revolving period the cooperatives employed for revolving back the allocated savings. Therefore, it was not possible to compute an average length of revolving period for the model I solutions.

Model I includes constraints that parallel closely the actual restrictions that managers and boards of directors observe in running the cooperatives. Thus, this model required that 20% of total patronage refunds be made to farmer-members in cash, annual cash payments from the revolving fund be equal to actual amounts revolved back to farmer-members, debt-equity ratios be 1.0 or less, and the current ratios equal or exceed 1.7. Debt-equity and current ratio constraints were omitted from models II through IX, since it was desired to see how much the solvency and liquidity ratios would vary under a full range of different financing plans. Moreover, conflicts among restrictions made it impossible to obtain mathematical solutions when liquidity and solvency constraints similar to those of model I were included in models requiring the highest cash patronage refunds.

Under models II through V (five-year revolving plan models), savings allocated to members in 1966, 1967, 1968, and 1969 were revolved back to them during 1971, 1972, 1973, and 1974, respectively. No capital was revolved back to farmer-members during 1966 through 1974 under models VI through IX, since the first payments under these ten-year revolving plan models would not have been due until 1975.

The LP analyses were based on figures for all 189 local supply cooperatives in Wisconsin. These local cooperatives sold feed, seed, fertilizer, hardware items, bulk gasoline, and petroleum products. The cooperatives were grouped into the size categories indicated in table 2 before making the analyses. LP results obtained for representative (average) firms from each size group were multiplied by appropriate expansion factors to draw inferences about the population of cooperatives.

Figures on sources and uses of funds required for the LP studies were obtained from various sources. Required balance sheet and

[a] Source: Cost coefficients for preferred stock, common stock, Bank for Cooperatives loans, commercial bank loans, other source loans, and certificates of indebtedness were obtained from financial statements of 189 Wisconsin farm supply cooperatives. Cost coefficients for allocated savings were obtained from Francl and Scheffel. The unallocated savings cost coefficients were obtained from Frattinger.
[b] Weighted average of cost coefficients used in LP models for representative firms from groups 1, 2, 3, and 4.
[c] Actual cost coefficients used in LP models for representative firms from all size groups.
[d] The 22% and 26% cost coefficients, respectively, are the federal income tax normal and surtax rates applicable to unallocated savings (reserves) of the cooperatives. These costs represent one-time charges assessed during the year in which the cooperatives accumulated the reserves.

operating statement figures for 1966 through 1972 for the 189 Wisconsin cooperatives were obtained from three regional cooperatives, private certified public accounting firms, and the local cooperatives themselves. The financial source and use figures for 1973 and 1974 were not yet available from these sources when this study was being conducted. However, possible effects on optimal solutions of the sharp rise in interest rates relative to preferred and common stock dividends that occurred during 1973 and 1974[5] seemed too important to ignore. Therefore, source and use of funds data for these two years were obtained by extrapolating the balance sheet and operating statement figures for 1966 through 1972 to 1973 and 1974. Cost coefficients used in the LP models (interest rates, preferred and common stock dividend rates, interest rates on certificates of indebtedness, etc.) for 1966 through 1974 were obtained from financial statements of the cooperatives and officials of lending agencies. Cost coefficients used for obtaining the 1966, 1970, and 1974 LP solutions appear in table 3.

In the LP models and also in computing capital costs for the existing financial structure, allocated savings (revolving fund) capital was priced at a level equal to the cost of short-term debt to farmer-members, a procedure similar to that used by Snider and Koller. The figures used in the study to represent the cost of short-term debt were weighted averages of short-term interest rates paid by Wisconsin farmers for short-term loans obtained from commercial banks and Production Credit Associations.[6] Assignment of this cost to allocated savings recognizes that member-

[5] For example, average interest rates charged by the St. Paul Bank for Cooperatives for seasonal and term loans averaged 5.88% in 1971 and 1972, only 1.14 percentage points higher than average preferred stock dividend rates paid by the Wisconsin farm supply cooperatives in this two-year period. In 1973 and 1974, the St. Paul Bank for Cooperative's interest rates for these same types of loans exceeded the preferred stock dividend rates paid by the cooperatives, which were lower than costs imputed to allocated debt relative to equity capital of the type just described would change substantially the optimal solutions and overall financing costs, it was thought to be important to include the 1973–74 period in the study to examine the effects of such changes.

[6] Allocated savings total a few hundred dollars or less for most Wisconsin farmer-members each year. If returned to the farmer, this money could substitute for short-term debt. Therefore, logic exists for pricing this capital at a cost equal to that for short-term debt. It can be argued that other types of equity capital such as preferred and common stock should be priced at the same rate as allocated savings. Actual stock dividend rates paid by the cooperatives, which were lower than costs imputed to allocated savings, were employed in the study for pricing stock, since these securities appeared to be a less risky investment for the farmer-member than allocated savings. For example, when a farmer-member retires or moves away from the trade area, some Wisconsin farm supply cooperatives will redeem his stock at par. This same farmer is less likely to be able to withdraw from the cooperative any allocated savings to which he may have a claim. The moderately greater liquidity and lower risk to the farmer on stock appeared to justify pricing this capital at the actual, lower dividend rates.

patrons may incur a relatively high opportunity cost when they supply capital to a cooperative. The assignment of this particular cost to revolving fund capital was a key aspect of the study that significantly influenced the results.

Special pricing and accounting procedures were used to accommodate the "artificial" cost represented by the interest charge placed on allocated savings. Interest charged on allocated savings is "artificial" in the sense that cooperatives typically do not actually pay this interest to farmer-members. Therefore, it can be argued that a cooperative's current liabilities should not be inflated by this interest charge. On the other hand, farmer-members do incur an opportunity cost on allocated savings retained by the cooperative. It is contended that a cooperative should consider this cost when deciding upon the mix of funds to use for financing growth and operations. The dilemma created by the dual character of this interest charge was resolved as follows: allocated savings were priced at the above mentioned short-term interest rate when computing the optimal financial structures with the LP models. Interest on allocated savings was included in the interest and dividends total in the balance sheets for the existing structure and those developed for the LP solutions.[7] However, in developing these balance sheets, the interest charges on allocated savings were subtracted from the other current liabilities figure to avoid creating an artificial net addition to current liabilities equal to this interest item.[8] This subtraction also performed the necessary function of keeping liabilities and equities equal to total assets on the balance sheets.

Results

Minimum Cost Capital Mixes

Use of allocated savings (revolving fund) capital was reduced substantially under the LP solutions. In the first LP solutions for the 1966–74 period, the models specified that long-term debt would be the primary substitute for revolving fund capital. However, the last solutions in the 1966–74 sequence called for financing needs of the cooperatives to be met to a greater extent by increased use of permanent equity capital (e.g., preferred and common stock) rather than revolving fund capital or long-term debt. Certificates of indebtedness comprised a substantial proportion of the long-term debt that remained in the last solutions in the sequence. Typically, financing costs were lower and cash patronage refunds substantially higher under the optimal solutions prescribed by the LP models than under the existing financial structure.[9]

Balance sheets for the existing financial structure and those compiled from the model II solutions for 1966, 1970, and 1974 for an average cooperative from the population of 189 firms appear in table 4. Results for model II (40% CPR, five-year revolving plan) are presented since they are representative of the optimal financial mixes prescribed by the various LP solutions and because it might be most feasible for cooperatives to follow prescriptions of model II, which call for relatively small departures from the present financing practices.

Financing costs (interest plus dividends) for the average cooperative under the model II solutions for 1966, 1970, and 1974, respectively, were $1,361 (7.1%), $2,522 (8%), and $3,306 (7.4%) lower than under the existing structure (table 4). Cash patronage refunds for 1966, 1970, and 1974, respectively, under model II were $3,899 (94.8%), $5,271 (90.8%), and $6,792 (83.8%) higher than under the existing structures.

Long-term debt totaled $55,822 (13.5% of total debt plus equity) under the existing structure in 1966. The model II solution for 1966 called for an approximate doubling of the amount of long-term debt to $112,141 (table 4). Allocated savings or revolving fund capital, which totaled $85,685 (20.8% of total debt plus equity) under the existing structure for 1966 was reduced to $12,020 (2.9% of total debt plus equity) under the model II solution for 1966 (table 4).

[7] It was necessary to include this interest charge in the existing balance sheets to make the existing balance sheet figures comparable to those developed from the LP solutions. This adjustment to existing balance sheets involved increasing the interest and dividends component of current liabilities by the amount required to price allocated savings at the short-term interest rate paid by farmer-members. Identical off-setting adjustments were made to the other current liabilities component of current liabilities to keep total current liabilities at actual levels.

[8] Other current liabilities include all current liabilities except interest and dividends, cash payments (cash patronage refunds) to farmer-members, and short-term loans from the Bank for Cooperatives, commercial banks, and other sources.

[9] The term "financial structure" as used here refers to the composition of debt and equity used by the cooperatives. Specifically, it refers to the amount of short- and long-term debt, certificate of indebtedness capital, preferred stock, common stock, allocated savings, and unallocated savings capital used by the cooperatives.

[a] Source: Existing structure balance sheet figures represent averages of actual balance sheet figures for the 189 Wisconsin farm supply cooperatives that provided data for the study. Model II balance sheet figures are weighted averages of balance sheet figures developed from the LP optimal solutions generated by model II for representative cooperatives from groups 1, 2, 3, and 4.

The model II solution for 1970 prescribed that the average cooperative should use $115,137 of long-term debt (20.3% of total debt plus equity). This represents a 16.3% increase over the amount of long-term debt in the existing structure for 1970. Allocated savings or revolving fund capital under model II for 1970 totaled $63,121 (11.1% of total debt plus equity) as compared to $116,333 (20.4% of total debt plus equity) under the existing structure.

Model II called for use of $137,317 (18.7% of total debt plus equity) of long-term debt in 1974, which was $5,722 less than under the existing structure. The solution for 1974 prescribed use of $86,246 of revolving fund capital. This figure, which represented 11.8% of total debt plus equity, was 44.7% less than the amount of revolving fund capital used in the existing structure in 1974. Long-term debt and revolving fund capital were displaced partly by preferred and common stock capital in the optimum solution for 1974. These two permanent sources of equity capital totaled $404,749 under model II in 1974, or 21.5% more than under the existing structure.

The prescriptions in the 1970 and 1974 solutions calling for increased use of preferred and common stock were not surprising in view of the increase in interest rates relative to stock dividend rates in the 1970–74 period. As expected, the relatively high opportunity cost attached to allocated savings (revolving fund) capital caused the model to prescribe that cooperatives should use substantially less of this type of capital. Cooperatives, of course, could find it difficult to follow the model's prescriptions since farmer-members might not wish to purchase additional stock, especially if interest rates exceeded stock dividend rates by several percentage points, as in 1974. However, members would have some incentives to purchase additional stock despite the lower return on these securities. First, up to $200 of the stock dividends could be exempt from federal income taxes under the Internal Revenue Service dividend exemption provided to husbands and wives filing joint tax

returns. Second, members might purchase additional stock if this helped to maintain the cooperative as a competitive element in the farm supply business. Fenwick contends that the latter point is important (p. 69). In his study, he assumes that farmers will accept returns on investments in their farm supply cooperative that are about five percentage points lower than those obtained from investments in their farm businesses in order to maintain the cooperative as a viable market force. Thus, especially in areas where the second incentive assumes importance, cooperatives might find it feasible to follow prescriptions of the type produced by model II.

Cumulative Changes in Financing Costs and Cash Patronage Refunds

Accumulated financing cost reductions for 1966 through 1974 for the nine LP solutions appear in table 5. Under the different models, financing costs were from 6% to 13% lower than under the existing financial structure. Average financing cost savings per firm for the 1966–74 period ranged from $18,737 (model I) to $36,519 (model V). Average annual savings per firm for models II and VI, which prescribe 40% minimum cash patronage refunds, respectively, were $2,307 and $1,870.

Lengthening the revolving period had only modest effects on financing costs. Financing cost savings under models II, III, IV, and V, which have five-year revolving plans, were only 6.7% larger for 1966 through 1974 than under models VI, VII, VIII, and IX, which have ten-year revolving plans. Financing costs were a little less under the five-year revolving plan models because the relatively expensive revolving fund capital was used for shorter periods under these models.

Accumulated cash patronage refunds for the different LP solutions ranged from 4.9% lower (model I) to 375.4% higher (models V and IX) than those for the existing structure (table 5). For models II and VI, the average annual increase per firm in cash patronage refunds for 1966 through 1974 were $5,670 and $5,733, respectively. Cash patronage refunds were nearly identical under models II, III, IV, and V (five-year revolving plans) and under models VI, VII, VIII, and IX (ten-year revolving plans).

Impact of Optimal Plans on Liquidity and Solvency of Cooperatives

Robert Morris Associates current ratios and debt-equity ratios for 110 to 150 farm supply firms located throughout the United States and Canada were employed as standards for judging whether the prescriptions generated

[a] Source: Figures on accumulated capital cost reductions and cash patronage refund changes were obtained from data generated by the LP optimal solutions for representative cooperatives from groups 1, 2, 3, and 4 and from existing financing cost and cash patronage refund data for the cooperatives. Existing financing cost and existing cash patronage refund data required for computing the accumulated changes were obtained from the financial statements of the 189 Wisconsin farm supply cooperatives which provided data for the study.

[b] Percentages represent total financing cost reductions for 189 firms expressed as a percentage of the accumulated total financing costs ($51,432,852) for the 189 firms under the existing structure during 1966–74.

[c] Percentages represent total changes in cash patronage refunds for 189 firms expressed as a percentage of accumulated total cash patronage refund ($10,691,019) under existing structure during 1966–74.

by the models would reduce liquidity and solvency of the cooperatives excessively. A Robert Morris Associates median ratio (e.g., median current ratio) represents the ratio that lies in the middle of a group of ratios arrayed from "strongest" to "weakest." The upper quartile ratio lies halfway between the median and "strongest" ratio in the array. The lower quartile ratio lies halfway between the median and the "weakest" ratio in the array.

Officials of banks and lending agencies use these standard ratios for appraising whether a firm is financially strong and credit-worthy. Lenders generally conclude that a firm has average financial strength if its current and debt-equity ratios are about equal to the corresponding Robert Morris Associates median ratios. They consider a firm to be financially strong if its ratios are near the Robert Morris upper quartile ratios and financially weak if its ratios are near the Robert Morris lower quartile ratios.

High liquidity (strength) is indicated by large values of the current ratio. On the other hand, low solvency (weakness) is associated with high values for the debt-equity ratio.

[a] Source: Current ratio and debt-equity ratio averages for 189 firms were computed from actual average balance sheet figures for the firms and from weighted averages of balance sheet figures generated by the LP optimal solutions for group 1, 2, 3, and 4 cooperatives. Average current ratios and debt-equity ratios for group 4 firms were computed from balance sheet information developed from the LP optimal solutions for the representative cooperative from group 4. Robert Morris standard ratios were obtained from Robert Morris, *Annual Statement Studies*.

[b] Standard ratios employed for appraising liquidity and solvency of the average cooperative from the group of 189 firms were based on average ratios reported by all farm supply firms from which Robert Morris Associates collects data.

[c] Standard ratios employed for appraising liquidity and solvency of group 4 cooperatives are based on average Robert Morris Associates figures for farm supply firms similar in size to the group 4 cooperatives.

[d] No Robert Morris Associates standard upper and lower quartile ratio figures were available for 1966.

Therefore, upper quartile value figures for the Robert Morris current ratio standards are larger than the median values, and upper quartile figures for the debt-equity ratio standard ratios are smaller than the median values (table 6).

The current ratios (used to measure liquidity) for the average Wisconsin farm supply cooperative fell below the Robert Morris Associates median ratios only under models V and IX, which specified that 100% of patronage refunds be paid in cash. Current ratios of the larger group 4 firms, whose liquidity was lower than average under the existing structure, generally fell below Robert Morris Associates median liquidity ratios for like-sized firms under plans II, III, IV, V, VI, VII, VIII, and IX, which called for payment of 40% or more of patronage refunds in cash. However, even for these plans, the current ratios of the group 4 firms still remained above the lower quartile Robert Morris Associates current ratios (table 6).

The debt-equity ratios (used to measure solvency) for the average Wisconsin cooperative remained below the Robert Morris Associates median values under models I thorugh IX. However, for the large group 4 firms, the debt-equity ratios for plans that called for payment of 60% or more of the patronage refunds in cash generally were higher than the Robert Morris Associates median figures.

The implication of the above is that it would be feasible for cooperatives to adopt alternatives to the commonly used 20% cash patronage refund plans. If the average cooperative used capital acquisition practices similar to those prescribed by the models, it generally could pay 40% or 60% cash patronage refunds without jeopardizing its solvency or liquidity.

Effects of Mandatory Equity Retirement Plans on Solvency of Cooperatives

Under the hypothetical mandatory equity retirement plan examined in the study, representative farm supply cooperatives would retire each year the equity capital of members who die, retire, or leave the area served by the cooperative and would replace the equity capital paid out to former members under the plan with long-term debt. Simulation of the impact of the plan involved modifying the balance sheets of the representative cooperatives from groups 1, 2, 3, and 4 to reflect effects on solvency of replacing the equity capital with debt. (A description of the size and number of cooperatives in each group is given in table 2.) In order to perform the simulation it was necessary to get estimates of the average amount of equity capital held by members who die, retire, or leave the cooperatives each year. The needed information (table 7) was obtained from telephone interviews of a stratified random sample of officials employed by 83 of the 189 Wisconsin farm supply cooperatives.

The statistic $Diff_2$ was used to measure how much solvency of the cooperatives would have declined if management had been required to replace the equity capital represented by the percentages in table 7 each year during 1966 through 1974 with long-term debt. $Diff_2$ equals the Robert Morris Associates median debt-equity ratio, $(D/E)_{ts}$, minus the debt/equity ratio of the representative cooperatives under the mandatory equity retirement plan, $(D/E)_{mer}$. Note that $Diff_2$, which goes negative when a cooperative's debt-equity ratio rises above the Robert Morris standards, became negative for all four representative cooperatives within two years after the mandatory equity retirement plan became operational (figure 1).

Solvency ratios declined most sharply under the mandatory equity retirement plan for the group 1 and 3 cooperatives, which had larger than average amounts of equity capital in their existing financial structures. The debt-equity ratios for the group 1 cooperative, for example, rose above the Robert Morris Associates lower quartile debt-equity ratios in 1973, indicating that solvency of the small firms in this group deteriorated substantially under the hypothetical equity retirement plan.

Statistic $Diff_1$ (figure 1) shows that the

Table 7. Average Percentage of Cooperative's Equity Capital Held by Members Who Die, Retire or Leave Trade Area Annually[a]

[a] Source: Figures were obtained from interviews of officials employed by 83 of the 189 Wisconsin farm supply cooperatives.

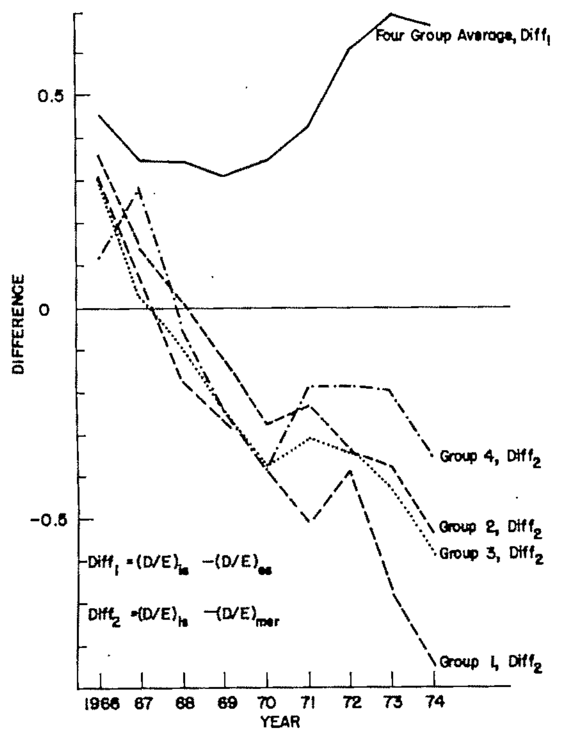

Figure 1. Comparison of Robert Morris Associates median debt-equity ratios to debt-equity ratios for existing financial structure and debt-equity ratios under mandatory equity retirement plan

mandatory equity retirement plan was not a factor that simply exacerbated an already deteriorating solvency condition among the firms. $Diff_1$ is the Robert Morris Associates median debt-equity ratio, $(D/E)_{ts}$, minus the actual average debt-equity ratio of the representative cooperatives, $(D/E)_{es}$. The positive and increasing values for $Diff_1$ (figure 1) show that actual debt-equity ratios for the average Wisconsin farm supply cooperative declined during 1966 through 1974 relative to the Robert Morris Standards. Thus, the mandatory equity retirement plan would have caused the decline in solvency in firms, which otherwise would have maintained strong solvency positions.

This study admittedly examined only one basic type of mandatory equity retirement scheme. However, many other proposed equity retirement plans do have similar characteristics and therefore might produce similar effects. For example, one other equity retirement plan would require cooperatives to retire each year the equity capital of members who die, retire, or move away from the cooperatives trade area and also pay off some proportion of the equity capital held by those members who left the organization in earlier years. Since retiring the equity capital of those who leave each year could substantially reduce solvency of farm supply cooperatives, any obligation to retire additional equity capital could put an especially heavy debt burden on the firms. The implication of this part of the study seems clear. Lawmakers who are considering mandatory equity retirement plans for agricultural cooperatives should examine whether enacting these bills into laws would place an excessive debt load on the cooperatives.

Summary and Implications

An optimal or least-cost financial structure for Wisconsin farm supply cooperatives would include more permanent equity capital (e.g., preferred and common stock), more certificates of indebtedness capital, and substantially less revolving fund capital. In the study the least cost financial mix included less revolving capital primarily because this capital was priced at a rate equal to the cost of short-term debt to recognize the opportunity cost incurred by farmers who supply capital to a cooperative. Financing costs under the least cost solutions for the 40% and 60% cash patronage refund plans were about \$2,100 (7%) and \$2,800 (9%) per year lower, respectively, than actual financing costs of the average Wisconsin farm supply cooperative during 1966 through 1974. The average cooperative might find savings of this size attractive since the firm could achieve these savings while increasing cash refunds to members by about 90% under the 40% cash patronage refunds plan and 185% under the 60% cash patronage refund plans.

The dynamics of achieving the optimal mixes would have the cooperatives use more long-term debt as an interim measure, while gradually increasing sales of preferred and common stock. Frequently, the market for a cooperative's stock is limited since capital appreciation and dividends on the stock are modest and restrictions exist on transfer of the stock. Therefore, farmer-members might need to be the primary customers for additional stock issued. Members would have these incentives to purchase additional stock. First, dividends on the stock might be attractive compared to returns on funds tied up in a

revolving fund that fails to revolve or revolves sporadically. Second, up to $200 of stock dividends each year would be exempt from federal income taxes. Finally, members might purchase stock that pays modest dividends if this helped to maintain the cooperative as a viable competitor in farm supply markets. Cooperatives, of course, also might need to pay moderately higher dividends in order to sell more stock. The amount that cooperatives would have to raise dividends to produce desired stock sales would vary from firm to firm and might be influenced by how much the farmer-member valued keeping the cooperative as a viable competitor and by the nonmonetary benefits secured from holding membership in the organization.

Liquidity and solvency of the average cooperative were satisfactorily maintained under the 40% and 60% cash patronage refund plans examined in the study. Therefore, if the cooperatives could succeed in selling the required amounts of stock, they apparently would find it feasible to develop financing plans that would lower sacrifices of members, reduce capital costs, and substantially increase cash patronage refunds.

Former members or inactive members would benefit if the farm supply cooperatives developed systematic plans for retiring the equity capital of members who die, retire, or move from the cooperative's service area. But if the cooperatives were required to implement equity retirement plans of the type considered in this study, this could substantially reduce the solvency of many of these firms.

Acreage Response and Demand for Processing Tomatoes in California

Wen S. Chern

A theory of contracting is developed to show how acreage and price might be determined in the raw tomato market. The paper estimates the structural parameters of the acreage response and demand for processing tomatoes facing California growers. Several hypotheses of leadership pricing are tested. Results show that the California processing industry can be characterized as a competitive industry, since the leadership pricing as observed is consistent with the competitive pricing. Acreage response is shown to be price elastic. The adoption of the tomato harvester is found to have a significant impact on acreage response.

Key words: acreage, contracting, econometric analysis, elasticity, leadership pricing.

Over the last two decades, California has been the most important state in producing processing tomatoes in the United States. In 1974, California produced 4.8 million tons of processing tomatoes, which accounted for 83% of the U.S. production. Most processing tomatoes have been produced under contractual arrangement in California. The market structure has been such that most processors commonly follow price leadership in negotiating contract price with growers (Collins et al.). The study develops a theory of contracting that shows how acreage and price might be determined in the raw tomato market and estimates the structural parameters of the acreage response and demand for processing tomatoes facing California growers.[1]

The major objective of this paper is to relate empirical results to several hypotheses of leadership pricing and to test whether the results are consistent with a particular theory. Also, the empirical results provide a basis for further analysis of the processing tomato industry.

Economic Analysis of Contracting

The analysis of contracting deals with the determination of acreage and price within the structure of the raw tomato market. Theoretically, acreage and price are determined by supply and demand, which can be derived from growers' and processors' profit maximization conditions.

A Static Economic Model

Define the following variables: A = acreage to be contracted, Y = yield per acre, Y^* = expected yield, $Q = AY$ = quantity produced from contracted acreage, $Q^* = AY^*$ = expected quantity to be produced, P_c = contract price per ton of raw tomatoes, and P_j^* = expected price of final product j.

Suppose that the growers' objective is to maximize profit subject to technological and contractual constraints. Begin with the production function $Q = Q(A, X_1, X_2, X_3)$, where X_1 is labor, X_2 is fertilizer, and X_3 is capital. It is assumed that all marginal products are nonnegative and Q is a strictly concave function (at least in the economically relevant region). Furthermore, the cost

[1] Theoretically, one cannot separate the demand for California processing tomatoes from the demand for the same product in other states. Fortunately, it was found that production in other states has been relatively stable without any significant trend over the period under consideration. The increasing trend of yield in other states has been offset by the declining trend in acreage. The fact that relatively constant production has prevailed in other states facilitates the treatment of the demand for raw tomatoes facing California growers.

function is specified as $C = k + w_0A + w_1X_1 + w_2X_2 + w_3X_3$, where k, w_0, w_1, w_2, and w_3 are, respectively, fixed-cost and input prices for A, X_1, X_2, and X_3.

The profit function can then be expressed as $\Pi_g = P_cQ - C$. The problem is to maximize Π_g subject to $Q \leq Q^*$, $A \geq 0$, and $X_i \geq 0$ for $i = 1, 2,$ and 3. This is a nonlinear optimization problem. Noting $Q^* = AY^*$, one can derive the solutions for A and the X_i's from the Kuhn-Tucker conditions for a maximum. The resulting equations are generally termed the input demand functions. Our major interest is in the equation for acreage, namely,

$$(1) \quad A^s = A^s(P_c, w_0, w_1, w_2, w_3, Y^*).$$

Equation (1) can be viewed as the derived demand function for acreage with respect to w_0. It can also be treated as a derived supply function of acreage with respect to P_c. In general, it can be termed the acreage response equation.

Consider next the processors' demand for acreage in tomato contracting. Since there are much fewer processors than growers in the industry, it is plausible to assume that the processors procure raw tomato supply in a so-called oligopsonistic market. The equilibrium conditions for an oligopsonistic entrepreneur are, in general, difficult to derive because the reactions of his rivals can hardly be predicted whenever he adopts a pricing policy. Fortunately, the situation in the California tomato industry might be more straightforward. The industry was typified by price leadership (Collins, Mueller, and Birch). As a result, most processors view price as given in negotiating a contract with growers. We focus here on the study of the behavior of price-taking processors.

The processor is faced with a two-stage decision process. First, he has to determine the total quantity of raw tomatoes that he needs. Then he has to estimate the acreage needed according to his expectation of yield.

Suppose all processed products can be measured in proportion to the raw tomatoes utilized; that is, $V_j = r_jQ_j$, where V_j is the quantity of the jth processed product, r_j is the product transformation ratio for the jth product, and Q_j is the quantity of raw tomatoes used for product j. Assume further that the processing cost function for the jth product is given by $S_j = S_j(V_j) = S_j(r_jQ_j)$. This cost function is net of the cost of purchasing raw tomatoes. Disregarding inventory, the processors' expected profit function at the time of contracting is formulated as

$$\Pi_p = \sum_{j=1}^{k} P^*_j r_j Q_j - \sum_{j=1}^{k} S_j(r_jQ_j) - P_c \sum_{j=1}^{k} Q_j.$$

From the first-order condition of profit maximization, one can derive the demand function for raw tomatoes as $Q_j = Q_j(P_c, P^*_j; r_j)$ for $j = 1, \ldots, k$. The total demand for raw tomatoes is simply the sum of the Q_j's. This can be expressed in a general form as

$$(2) \quad Q^d = \sum_{j=1}^{k} Q_j = Q^d(P_c, P^*_1, \ldots, P^*_k; r_1, \ldots, r_k),$$

where $r_1, \ldots, r_k$ are fixed parameters in the equation.

In order to make contracts with growers, the processor has to decide on specific terms in regard to acreage. Since yield is not known at the time of contracting, acreage has to be derived according to the yield expectation:

$$(3) \quad A^d = Q^d/Y^*.$$

The acreage response function was derived from a single-product production function. While the treatment of a multiproduct production function would substantially complicate the theoretical model, it can be implemented in our empirical analyses by introducing the prices of competing crops in the acreage response function.

The static model as developed so far has not considered the effect of technological change. The adoption of the tomato harvester in the late 1960s has drastically altered harvesting operations. It is, therefore, important to know the extent to which the mechanization in harvesting has changed the structural parameters in both acreage response and raw tomato demand functions.

Price Determination

Stigler has classified two general cases of price leadership. One is the dominant firm leadership, and the other is the barometric firm hypothesis. In the former case, a dominant firm sets the price, while the minor firms buy what they wish at this price. The price leadership in the other case refers to the existence of a firm that conventionally first announces price changes that are usually followed by the other firms in the industry, even though the barometric firm may not occupy a dominant position.

As noted by Collins et al. and by our own observation through informal interviews with growers, the barometric type of price leadership has been commonly exercised in the Californian tomato industry. It is known that the price set by the leader firm may be competitive, monoponistic, or somewhere in between. If the leader firm fully complies with the market situation and sets a competitive price, the market can be viewed as a more or less competitive market in which A, Q, and P_c are simultaneously determined. If the contract price, P_c, is solely determined by leadership firms in a noncompetitive situation, it is exogenous in the system.

Treatment of Unobservable Variables

Expected yield and expected product prices in equations (1) and (2) are not observable at the time when growers and processors are negotiating for a contract. It is, therefore, necessary to know how growers and processors form their expectations.

It seems reasonable to assume that the grower formulates his yield expectation according to past yields. Nerlove has postulated an adaptive expectation model that leads to a geometrically declining lag formulation. Behrman later extended Nerlove's model by introducing an additional factor to account for abnormalities in rainfall. All these elaborated expectation models are difficult to implement in the present study because the number of independent variables is fairly large in the acreage supply equation and consequently the problem of degrees of freedom will be severe. For this reason, the following formulation is proposed:

$$E(Y_t|Y_{t-1}, \ldots) = \sum_{i=1}^{n} \lambda_i \, Y_{t-1},\ n = 2, 3, \ldots,$$

where λ_i's are some weights to be specified and $\Sigma\lambda_i = 1$.

The grower is subject to risk while making yield predictions. The mean-variance criterion has been widely adopted in measuring risk (Tobin, Behrman). This criterion appears to be the most relevant approach for application in this study.

Prices of processed tomato products are not observable at the time of contracting. However, information on current prices and inventory conditions could be used for predicting future prices. Also, the level of consumer incomes for the coming season could be easily projected. Therefore, it seems plausible to assume that $P^*_j = f(R_1, \ldots, R_k, I_j, M)$, in which R_j is the current price of jth product, I_j is the inventory at the time of contracting, and M is the projected consumer income. The important aspect of risk is not investigated for product prices because product prices are relatively more certain than yield, especially when price of raw tomatoes is under contract.

Econometric Variables

The preceding conceptual analysis has derived the fundamental functional relationships describing the California tomato economy. Before preceding with estimating these relationships, it is important to discuss the specific variables used in the analysis.

The first structural equation is acreage response, in which contract acreage, A_c, is expressed as a function of grower price, P_c, wage rates, Z_2, adoption rate of the tomato harvester, Z_4, price of ammonium nitrate, Z_5, average yield of the preceding three years, Y_a, standard deviation of yields in the preceding three years, D, and lagged prices of competing crops including sugar beets, $S_{p,t-1}$, grain sorghum, $G_{p,t-1}$, and alfalfa hay, $H_{p,t-1}$.

Grower prices are average prices of tomatoes purchased from contracted acreage. Wage rates for the preharvesting period are used because complete data for the harvesting period are not available. Since June is the peak month for labor demand in preharvesting operation, the wage rate in June is used for analysis. The average of wage rates in San Joaquin and Yolo counties (two major counties in producing tomatoes) is taken as the average rate for the state. The reported price of ammonium nitrate in California is used as the input cost of fertilizer.

Several formulations of yield expectation were tried in the preliminary analyses. The average yield of the preceding three years was found to be superior to using a one-year lag or the average of the preceding two years. Correspondingly, the standard deviation of the yields in the preceding three years is taken as the indicator measuring risk in yield expectation.

Due to a large number of alternative crops found in the major tomato-producing counties, it is rather difficult to single out the one or two most important competing crops. Sugar

beets, grain sorghum, and alfalfa hay were considered to be more important competitive crops and therefore were chosen for our empirical analysis.

Virtually all tomatoes were harvested by hand before 1963. In contrast, more than 95% of processing tomatoes have been harvested by mechanical harvesters since 1968. The period 1964–67 was a transition period with mechanical harvesting gradually replacing hand harvesting. The degree of mechanization is measured by the adoption rate of the tomato harvester.

The second structural equation is the demand for processing tomatoes, Q_c, expressed as a function of grower price, P_c, total April 1 inventory of five major tomato products, Z_7, the weighted FOB price of five major tomato products, R, and per capita consumer incomes, Z_{10}.

The total quantity demanded, Q_c, cannot actually be observed at the time of contracting. An approximation is therefore required. To a limited extent, open market purchases can be used by the processor to fill the gap between the desired quantity and the actual quantity produced from the acreage to be contracted. Thus, the sum of the quantity from the contracted acreage and the quantity purchased from the open market is taken as the quantity indicator of the processors' demand at the time of contracting.

Due to the limited degrees of freedom from the relatively small sample size, it is not feasible to include the prices of all processed tomato products in the demand equation. Contracts are generally made in the period January through April before each season starts. Assuming that processors utilize the most recent information about the prices of tomato products for their decisionmaking, the weighted average FOB price, R, is computed as

$$R = \sum_{j=1}^{5} \beta_j R_j,$$

in which R_j is the average FOB price of product j during January through March, β_j is the weight specified as the percentage of total shipments of product j (in a standardized 24/303 case basis) during this period, and the five products are canned tomatoes, tomato juice, paste, puree, and catsup.[2]

The last two variables affecting the processors' demand for raw tomatoes are inventory and consumer incomes. To conserve degrees of freedom, the sum of the April 1 inventories of the five major products is used. Furthermore, the actual seasonally adjusted annual averages (in fiscal years) of disposable personal incomes are used as the projected figures at the time of contracting.

The final behavioral equation is the quantity-acreage relation expressing A_c as a function of Q_c and Y_a.[3]

Empirical Results

In California, tomato production has been concentrated in ten major counties, which have accounted for more than 85% of the state's production in recent years.[4] In this paper, only the empirical results obtained from the analysis based on these ten counties are presented, even though the results obtained for the state as a whole show no significant differences (as reported in Chern).[5]

Annual econometric models for the post-World War II period 1951–72 are constructed. Both linear arithmetic and linear logarithmic forms were tried as alternative functional specifications. It was found that in most cases both formulations performed equally well. However, only the results of logarithmic form are presented here. The adoption rate of the tomato harvester, Z_4, would not take a logarithmic transformation because its values are zero for many years.

One important aspect of our empirical analysis is the investigation of the behavior of the grower price, P_c, in the system. As pointed out previously, under the noncompetitive leader-firm pricing hypothesis, the grower price is determined solely by a leader firm and is exogenous in the system. Consequently, the structural equations can be appropriately estimated by ordinary least squares (OLS) under the usual condition (i.e., the variance-covariance matrix $\Sigma = \sigma^2 I$) about the disturbance terms. On the other hand, if the raw tomato market follows more or less a competi-

[2] Tomato sauce is not included because complete data on its shipments are not available.

[3] A_c is measured in thousand acres, Q_c in thousand tons, P_c in dollars per ton, Z_2 in dollars per hour, Z_4 in percent, Z_8 in dollars per ton, Y_a in tons per acre, D in tons per acre, $H_{p,t-1}$ and $S_{p,t-1}$ in dollars per ton, $G_{p,t-1}$ in dollars per bushel, R in dollars, Z_7 in 24/303 million cases, and Z_{10} in billion dollars.

[4] The ten counties are San Joaquin, Yolo, Fresno, Solano, Sutter, Sacramento, Stanislus, Merced, Santa Clara, and San Benito.

[5] Thus, A_c and Q_c are, respectively, contract acreage and purchased quantity of tomatoes in the selected ten counties. However, for all other variables, state data are used. Complete data used in this study are available in Chern.

[a] OLS estimate is the same as in 2.1.

[b] OLS estimate is the same as in 3.1.

tive market system, the grower price is then determined at the equilibrium conditions where demand equals supply. A simultaneous equation system is appropriate and, hence, the structural equations have to be estimated by simultaneous system approaches. Under the usual conditions, both two-stage least squares (2SLS) and three-stage least squares (3SLS) give consistent estimates of the structural coefficients. Since 3SLS is theoretically more efficient than 2SLS, only 3SLS estimates are presented.[6]

Estimated Structural Equations

Table 1 contains the final sets of estimated equations.[7] With a few exceptions, all estimated coefficients appearing in the equations presented in table 1 have a t-ratio greater than two.[8] The variables Z_4, D, and $Z_4 \ln P_c$ are sensitive to estimation methods. Specifically, Z_4 is significant only when 3SLS is applied. Since Z_4 is an important variable for making inferences about the impacts of harvesting mechanization and D is an interesting variable for measuring risk, the presentation of some variants with and without these two variables appears to be warranted. The interaction variable, $Z_4 \ln P_c$, is included to investigate whether the introduction of tomato harvesters

[6] The differences between 2SLS and 3SLS estimates are notable in some cases, and in general the coefficients estimated by 3SLS are slightly larger in absolute value and the estimated standard errors are smaller than those obtained by 2SLS.

[7] Detailed results obtained from a systematic elimination of insignificant variables from the entire set of variables originally proposed are available in Chern. As turned out, the model failed to identify crops competing with processing tomatoes. This is perhaps because there are too many alternative crops, and hence no single crop can show a significant impact at the aggregate level. Further investigation at the county level is currently under way and will be reported elsewhere.

[8] The reliability of an estimated coefficient can be established by carrying out the student t-test. It is well known that the t-test and the Durbin-Watson statistic are strictly valid only when OLS is applied. The standard errors for the 3SLS estimates refer to asymptotic distributions and their validity in small samples is not generally known.

has affected the price elasticity. Unfortunately, the extremely high correlation between Z_4 and $Z_4 \ln P_c$ precludes a possible formulation to include these two variables in the same equation. For the purpose of comparison, they are separated out in two equations as shown in equations (1.1) and (1.2).

Consider the highlights of our findings. The first equation set consists of three structural equations. Equation (1.1) shows that grower price, $\ln P_c$, wage rates, $\ln Z_2$, fertilizer price, $\ln Z_5$, and lagged average yield, $\ln Y_a$, are significant factors influencing the grower's acreage response as estimated under both methods. The adoption of mechanical harvesters, Z_4, shows a significant impact only when 3SLS was applied. In equation (2.1), all three variables, i.e., grower price, $\ln P_c$, weighted FOB price of tomato products, $\ln R$, and consumer incomes, $\ln Z_{10}$, are significant in determining the demand for processing tomatoes. Finally, equation (3.1) shows that the processor demand for acreage is plausibly explained by its expected yield, $\ln Y_a$, and quantity demanded, $\ln Q_c$.

Primary interest lies in the equations of acreage response and demand for processing tomatoes. The most important variable under investigation is, of course, the grower price, P_c. The most crucial variable for comparing different estimation methods appears to be P_c in the demand function for processing tomatoes. As shown in equation (2.1), the coefficient of $\ln P_c$ estimated by OLS is -0.25, which is substantially smaller in absolute value than the 3SLS estimate, -0.70.

When OLS is applied, the multiple coefficient of determination R^2 measures goodness of fit. Under 3SLS, R is the correlation coefficient between the actual and estimated values of the normalized variable. In general, R^2's are reasonably high, indicating good performance of the model. The Durbin-Watson test for OLS estimation does not suggest presence of positive first-order serial correlation except perhaps for equation (3.1), in which this statistic falls into the inconclusive region.

The second set of equations differs from the first set only in that Z_4 is replaced by $Z_4 \ln P_c$. The estimation of the demand for processing tomatoes and the acreage-quantity relation remains unchanged when OLS was used. In the acreage response equation, no significant changes were found. The estimated coefficient of $Z_4 \ln P_c$ has a reasonably high t-ratio only when 3SLS is used.

Variables Z_4, $\ln D$, and $Z_4 \ln P_c$ do not appear in the last set of equations. The elimination of these variables does not disturb the OLS estimates of equations (2.3) and (3.3), which remain unchanged from equations (2.1) and (3.1). The effects on the OLS estimates of equation (1.3) are also minimal. A fairly dramatic "improvement" is found for the estimated coefficient of the grower price in the demand equation when 3SLS is applied. The 3SLS estimate of the grower price coefficient (elasticity) become greater than one in absolute value, and the t-ratio is much improved.

Based on the estimated standard errors of estimated coefficients and on R^2, the model has performed fairly successfully in estimating the structural equations. The selection of particular estimation methods was made largely on a priori grounds according to the assumed market system. Therefore, the performance of various estimation procedures might be used as an informal test of hypotheses that we have made regarding market structure. Since the OLS estimate of the coefficient of P_c in the demand equation is not statistically significant, the simultaneous equation model appears to be more appropriate than the single-equation specification. In other words, the California processing industry can be characterized as a more or less competitive industry in the sense that the leadership pricing as observed is consistent with the competitive pricing.

Comparison of Elasticities

One of our objectives is to obtain estimates of the important elasticities for acreage response and demand for processing tomatoes. The knowledge of these elasticities would be quite useful for further policy analyses (e.g., Schmitz and Seckler). Since the results presented earlier appear to be sensitive to estimation methods, it would be of some importance to point out the extent to which the resulting elasticities differ.

Price elasticities estimated by OLS are substantially smaller than those estimated by 3SLS.[9] Specifically, results indicate that acreage response has a unitary elasticity using OLS and is elastic (1.7) using 3SLS.[10] The

[9] This holds also when arithmetic form is used. It is also found that the price elasticities obtained from the arithmetic specification are consistently smaller than those obtained from their comparable equations in logarithmic form.

[10] In dealing with the supply response of planted acreage of processing tomatoes, Babb, Belden, and Saathoff estimated the short-run and long-run price elasticities, respectively, as 2.18 and

exclusion of Z_4 and D from the system results in greater estimates of demand elasticities with respect to grower price as well as weighted product price. Furthermore, demand elasticities with respect to grower price estimated by OLS are substantially smaller (in absolute value) than those estimated by 3SLS. The results in equation (2.3) show that the demand for processing tomatoes has a unitary elasticity with respect to grower price as estimated by 3SLS and is inelastic using OLS estimation. Moreover, demand is elastic with respect to tomato product prices, R, and inelastic with respect to consumer incomes, Z_{10}, in all cases.

In order to derive the relevant elasticities associated with the processors' demand for acreage, it is necessary to consolidate the demand for raw tomatoes and the acreage-quantity relation. The acreage demand elasticities can be obtained simply by multiplying the relevant coefficients in the demand equation for processing tomatoes by the coefficient of $\ln Q_c$ in the acreage-quantity equation. Using estimated equations (2.3) and (3.3), the resulting elasticities for acreage demand are presented in table 2. The elasticities of the demand for acreage are uniformly smaller than the elasticities of the demand for processing tomatoes. However, the differences between these two sets of elasticities are quite small.

Impacts of the Adoption of the Tomato Harvester

Mechanization is generally regarded as a labor-saving technological innovation. The adoption of the mechanical tomato harvester has changed the cost structure considerably for harvesting tomatoes (King, Jesse, and French). Since the underlying production function was essentially altered by this technological change, it is important to know whether the introduction of the tomato harvester has made any drastic structural changes in growers' acreage response. Variable Z_4 was included to reflect the impacts of harvesting mechanization, as shown in equation (1.1) in table 1.

As noted earlier, the coefficient of Z_4 is not statistically significant when the acreage response equation was estimated by OLS. The 3SLS estimate of this coefficient has a larger magnitude and a higher t-ratio. The numerical impact on acreage response can be calculated from equation (1.1). Since the largest value that Z_4 can have is 100, the maximum impact of the adoption of the tomato harvester is an increase of 51,000 acres for the selected ten counties.[11]

4.49 for Indiana, and 1.05 and 2.65 for Ohio, using the annual data for 1946–65.

Table 2. Derived Elasticities of the Processor Demand for Acreage

Estimation Method	Elasticities with Respect to: Grower Price P_c	Product Price R	Income Z_{10}
3SLS	−1.042	1.531	0.563
OLS	−0.202	8.23	0.490

It is of some importance to investigate whether the adoption of the mechanical harvester affected other structural parameters. Our primary concern is with price elasticity. A cross-product term of $Z_4 \ln P_c$ was introduced to account for this impact. As noted earlier, the extremely high correlation between Z_4 and $Z_4 \ln P_c$ made it inadvisable to carry both variables in the same equation. Results with only the cross-product term included are presented in equation (1.2) in table 1.

Under the present specification, price elasticity, E, at the mean values is decomposable into two components as $E = c_1 + d_1\bar{Z}_4$, where c_1 and d_1 are estimated coefficients of $\ln P_c$ and $Z_4 \ln P_c$, respectively, and $\bar{Z}_4$ is sample mean. Computed in this manner, the two components of the price elasticity are shown in table 3. Results show that the impact of the adoption of the mechanical harvester on price elasticity is, on the average, numerically small.

Since Z_4 has taken the maximum value (100) from 1971 on, it is of greater interest to deter-

[11] Based on the estimated equations in arithmetic form, the maximum impact at the sample means is estimated to be 54,000 acres. In 1972, these ten counties had a total of 158,000 acres contracted.

Table 3. Price Elasticity Components of Acreage Response of Processing Tomatoes

Estimation Method	Elasticity Components: $\ln P_c$	$Z_4 \ln P_c$	Total
	Computed at the Mean Values		
3SLS	1.658	0.034	1.692
OLS	0.883	0.018	0.901
	Computed for 1971		
3SLS	1.658	0.112	1.770
OLS	0.883	0.060	0.943

mine the full impact of this technical change by computing the elasticity components for 1971. This computation is carried through by using the actual value of Z_4 in 1971. The resulting elasticity components are also shown in table 3. It was found that the maximum effects of mechanizing harvesting on the growers' response to price changes generally appear to be small. Full mechanization in harvesting would raise the price elasticity by 6% of the total price elasticity under 3SLS and 7% by OLS.

Concluding Remarks

Results show that the 3SLS estimates of structural coefficients were, in general, more plausible than OLS estimates. In particular, the OLS estimates of the grower price coefficients were consistently lower in magnitude than the 3SLS estimates.

Estimated acreage response and demand elasticities were found to be sensitive to estimation method. The OLS estimates always resulted in a smaller elasticity in absolute magnitude than those estimated by 3SLS. Acreage response was shown to be price elastic by 3SLS but inelastic by OLS. Since for the last twenty years, tomato acreage has increased drastically in California, while it declined rapidly in other states, one would expect an elastic acreage response to price changes. This supposition is supported by the results obtained from the 3SLS procedure, but not by the OLS estimates. These results suggest that a competitive market might be appropriate in describing the California tomato economy, even though leadership pricing is commonly exercised.

The adoption of the tomato harvester was found to have a significant impact when the acreage response was estimated by 3SLS. When it has a significant coefficient, the maximum impact of this technological innovation is calculated to be an increase of 51,000 acres for the selected ten counties. Results also show that the impact of the adoption of the mechanical harvester on price elasticity is, on the average, numerically small. This may be attributable to the fact that California tomato growers in general have large acreage, and therefore, the purchase of a harvester may represent only a small fraction of their total investment. Furthermore, in a preliminary analysis of the pooled county model, Chern found that growers' price response was very high even before the harvester was introduced. Thus, additional price sensitivity induced by the adoption of the harvester is unlikely to be significant relative to the existing level of price response.

Estimation of Demand for Transportation of Agricultural Commodities

Walter Miklius, Kenneth L. Casavant, and Peter V. Garrod

A logit model is used to estimate the elasticities and cross elasticities for freight transport services. The model is applied to a sample of cherry and apple shipments. The performance of the model in explaining choice of transportation method is highly satisfactory. Estimated coefficients, with one exception, have expected signs and are statistically significant.

Key words: apples, cherries, logit, transportation.

A knowledge of demand of transport services is essential for regulatory as well as management purposes. A recent report notes that one of the principal activities of the Interstate Commerce Commission is to allocate traffic among the different transport modes. Since it lacks the power to issue quotas, it has to do this through the exercise of its power over rates. This, in turn, requires the knowledge of elasticities and cross elasticities of demand for transport service of each mode not only with respect to rates but also with respect to various quality of service characteristics (Task Force on Railroad Productivity, p. 190).

The same report provides an illustration for the need of similar information for management purposes. It recommends that railroads operate shorter trains on more frequent schedules as a means of reducing transit time and its variance. It asserts that the demand is responsive to improvement of service, i.e., more frequent train schedules will generate new traffic presumably more than offsetting high costs (pp. 300–306). Evaluation of this recommendation would require empirical estimates of the elasticity of demand for rail transportation with respect to freight rates, transit time, and its variance.

Walter Miklius is a professor of economics and agricultural economics and Peter V. Garrod is an assistant professor of agricultural economics at the University of Hawaii; Kenneth L. Casavant is an associate professor of agricultural economics at Washington State University.

Scientific Paper 4299, Project No. 0191, Washington State University, College of Agriculture Research Center. Partial support for this study was received through a grant from the Economic Research Service, U.S. Department of Agriculture. The authors wish to thank John Baritelle, Moheb Ghali, and David Price for comments on earlier drafts of this paper.

Decisions such as these affect not only the financial position of carriers but also incomes of producers of commodities transported and the regional specialization in production. These effects are particularly important in agriculture since agricultural commodities typically move longer distances to the markets and the cost of transportation accounts for a larger percentage of the value of commodity at destination.

Several past attempts at empirical estimation of freight-transport demand functions ran into conceptual, data, and estimation problems (Benishay and Whitaker, Limmer, Miklius, Perle, Sloss). In recent years, however, considerable progress has been made in estimating the demand for urban transport services. Here, the logit model was found to provide the most satisfactory general approach. In this paper we apply the logit model to estimate the elasticities and cross elasticities of demand with respect to prices and the quality of service characteristics of the transport modes.

Adoption of this model for estimating the demand for freight-transport services is discussed in the next section. More complete discussion of the model is available (Miklius and Casavant), and an extensive bibliography is presented by McFadden (1974). The model was applied to two sets of data—a sample of cherry shipments from Washington, Oregon, and Montana and a sample of apple shipments from Washington. The selection of variables is discussed and the empirical results are reported in the two sections that follow. The

sources and nature of data used are described in the appendix.

Cherries were selected because of their high perishability. It was expected that the quality of service, such as the transit time, would be a major factor in selection of the transport mode. Apples, on the other hand, are storable for longer periods of time, and, therefore, the selection of transport mode for their shipments should be more responsive to the differences in transport charges.

The Model

Each firm is faced with a large number of decisions. For the purpose at hand, however, we are mainly interested in a set of purchasing decisions. The reason for the focus on purchasing rather than sales decisions is the predominance of the "FOB shipping point" type of sale, in which the choice of the transport mode rests with the buyer rather than the seller.[1]

For each individual transaction, the four following decisions have to be made by the buyer: whether or not to purchase some of the commodity, what quantity, from what production area or marketing center, and what transport mode to use for shipment. The analysis of the complete decision process is beyond the scope of the present study. However, if buyers' decisions could be assumed to follow the sequence indicated, we could examine the choice of transport mode independently of other decisions. This is equivalent to an implicit assumption that the decision on whether or not to purchase a particular commodity, the size of shipment, and its origin are not affected by performance characteristics (i.e., freight rates, transit time, etc.) of the transport modes.[2]

The logit model has been modified to handle choices among unranked alternatives (McFadden 1968). The decisions to purchase from different production areas, therefore, could be analyzed concurrently with the choices of transport mode. For this initial effort, however, we have limited our analysis to the choices of transport mode.

The essence of the approach is as follows. For each shipment, the buyer is assumed to be faced with a set of mutually exclusive choices, which may include truck, rail, piggyback, and air. Examination of variables influencing these choices allows an estimation of probability that for a given shipment the buyer will make a particular choice. This, in turn, allows statements analogous to ordinary elasticity of demand statements to be made. The problem is to estimate the relationship between the specified explanatory variables and the choice made. For estimation of the demand for freight transport services the logit model could be specified as follows:

$$\log[p/(1-p)] = \alpha + \beta_{1i}C_i - \beta_{1j}C_j + \beta_{2i}T_i - \beta_{2j}T_j + \beta_{3i}VT_i - \beta_{3j}VT_j + \sum_{k=1}^{t}\gamma_K s_K,$$

where the dependent variable is known as "the logit" corresponding to the odds ratio in favor of mode i, C_i and C_j are the freight charges for each competing transport mode, T_i and T_j are their transit times, VT_i and VT_j are their variance of transit times, and s_K is the "kth" shipment, buyer, or seller characteristics considered relevant to the choice of transport mode.

The above model enables us to infer the choice of transport mode from the data on performance attributes of each mode and characteristics of shipments. The model can accommodate any number of alternative choices. The shipments by air and piggyback, however, still account for a relatively small proportion of all shipments, and none were selected in the sample used for estimation. The problem, therefore, was reduced to a binary choice: truck versus rail.

Selection of Variables

Although the choice of variables was affected by data availability, each selected variable has some a priori causal basis.

The rail and truck freight charges are used as two separate variables. Expected signs are those of normal price variables, i.e., the probability that a given transport mode will be chosen is negatively correlated with its own freight charge and positively with the freight charge of the competing mode.

The transit time refers to the promised rather than actual transit time, and it is usually

[1] According to the 1972 Northwest cherry crop survey, the FOB sales made up 87% of the cherry volume. Similarly, 91.5% of the total volume of apples in 1969–70 were sold on an FOB basis (Podany, Bohall, and Pearrow, p. 32).

[2] A somewhat similar problem is encountered in urban transport demand studies because of interdependence between the decision regarding choice of transport mode and the choice of location of home and choice of car ownership. This difficulty is avoided by specifying that the study is concerned with the decisions made after the home location and car ownership are already established.

quoted in days rather than hours, e.g., "third morning delivery," "fourth morning delivery." The expected signs of the transit time variables are determined by a number of factors that depend on the nature of the commodity being shipped. For a highly perishable commodity, where costs associated with time in transit are high, the probability that a particular mode is chosen is expected to be negatively correlated with its own transit time and positively correlated with the transit time of competing modes.

For readily storable commodities, the probability that a given mode will be selected may be either negatively or positively correlated with its own transit time. For shipments into inventory of batch- (or seasonally) produced commodities, in absence of unpredictable shifts in demand for commodity, the expected sign would be positive since the transit time is merely a substitute for the time in inventory. The buyer would choose the slower mode, *ceteris paribus,* as shipping charges implicitly incorporate costs of storage that would be a direct cost to the buyer if a faster mode was chosen. With unpredictable shifts in demand for commodity the sign may be negative, i.e., a buyer would prefer faster transit time mode if the value of loss function due to stockout exceeds the difference in freight charges. Furthermore, inventories could be held either by buyers or by sellers. Holding specialized inventories at shipping points is probably cheaper. Thus, a buyer could reduce his inventory holdings, thereby increasing the probability of a stockout and the probability of shipping by faster mode. The observed signs of the transit time coefficient would depend on the strength of the two opposite effects.

The dependability of transit time is widely regarded as an important determinant of model choice (Woods and Domenchich, pp. 25–34). Its quantification, however, proved to be somewhat of a problem. Although actual transit time for each cherry shipment was available, the number of observations to different destinations was not sufficient to test for the differences in reliability of delivery time. In addition, there may be a difference between actual variability of transit time and the variability perceived by the shippers (Bayliss, pp. 30–32). Thus, for lack of any suitable alternative, the variability of transit time had to be left out in estimation of the model for cherry shipments.

In the sample of apple shipments, the identity of the buyer of each shipment was known. This allowed us to conduct a supplementary survey of buyers who asked two hypothetical questions. (*a*) Suppose that you shipped 100 truckloads of apples. How many of these shipments would arrive on the promised day, one day late, two days late, etc.? (*b*) Suppose that you shipped 100 rail carloads of apples. How many of these shipments would you expect to arrive on the promised day, etc.? The responses to these questions may be interpreted as the subjective probability functions, and the mean of each function could be used as a proxy variable for the value of truck and rail transit time variability, respectively. This procedure, however, assumes a linear loss function; i.e., the value of a two-day delay is assumed to be equal to the sum of the values of two one-day delays. To avoid this linearity, the subjective probability functions could be weighted by square of the delay. Both variables, identified as "expected delay" and "expected cost of delay," were used in alternative estimations of the model.

Two additional variables were added in estimation of the model for cherry shipments. The value of commodity variable was included to account for a possible shift of demand for transport services during the shipping season. One would expect the value of transit time to be positively correlated with the value of commodity for several reasons. First, since one of the costs involved in a longer time in transit is interest, it depends on the value of the shipment (Meyer et al., p. 192). Second, the price changes during the shipping season follow a typical pattern of starting with a relatively high price at the beginning of the season, followed by a rapid decrease at first and a more gradual decrease until some minimum is reached with prices rising gradually thereafter until the end of the season. The probability of a sharp drop in prices, therefore, is greater at the beginning of the season when the prices are higher. For both of these reasons, one would expect the willingness of buyers to pay higher freight rates in exchange for faster transit time to be correlated with value of commodity.

The second variable, the age of pack, was added to serve as a proxy variable for the quality of cherries prior to shipment. It is expected that cherries that have been in storage prior to shipment would move, other things being equal, by a transport mode with a shorter transit time.

Table 1. Elasticities and Cross Elasticities of Demand for Rail and Truck Transportation of Cherries

Variable	Coefficient	t-ratio	Elasticity or Cross Elasticity for Rail Service	Elasticity or Cross Elasticity for Truck Service
Rail freight charges	−0.0161	5.6701	−2.8696	4.1466
Truck freight charges	0.0040	2.8060	1.1484	−1.6594
Rail transit time	−2.3438	6.6594	−5.5678	8.0454
Truck transit time	2.7822	4.9945	4.1194	−5.9524
Age of pack	−0.3775	5.5102	−0.4660	0.6732
Gross value	−0.0006	5.0270	−1.3133	1.9008
Constant	6.4788	6.6264	—	—

Empirical Results

The results of cherry shipments are shown in table 1. The reported coefficients are the maximum likelihood parameter estimates with respect to the log of the odds ratio in favor of rail transport, derived by an available computer program (Nerlove and Press). Since the model is symmetrical, the coefficients with respect to the odds ratio in favor of truck transport would have the same values but the opposite signs (Theil). The estimated elasticities and cross elasticities are analogous to the ordinary elasticity of demand and can be easily derived from the estimated coefficients. The elasticity of demand with respect to the ith variable is defined as $\frac{dQ}{dX_i}\frac{X_i}{Q}$. This can be expressed in terms of the elasticity of probability by writing $\frac{dQ}{Q}\frac{X_i}{dX_i} = \frac{d(pS)}{pS}\frac{X_i}{dX_i} = \frac{dp}{dX_i}\frac{X_i}{p}$, where p is the probability and S the total number of shipments. It can be shown that $\frac{dp}{dX_i}\frac{X_i}{p} = \beta_i X_i(1-p)$, where β_i is the estimated logit coefficient.[3] The estimated elasticities are reported in the last two columns of table 1.

The statistical results are very encouraging. All coefficients have a priori expected signs and are significant at the 1% level using the normal approximation.[4] To assess the overall explanatory power of the model, the likelihood-ratio test was used to test the hypothesis that all estimated coefficients are equal to zero. The χ^2 was equal to 301.42, above the critical value of 18.55 for six degrees of freedom. Thus, the hypothesis that the parameters are equal to 0 was rejected. Furthermore, the elasticity estimates are plausible. The demand for both rail and truck transport service is relatively elastic not only with respect to its own transit time and freight charges but also with respect to those of the competing mode. As could be expected for a highly perishable commodity like cherries, the choice of transport mode is much more sensitive to the transit time than to freight charges.

The results for apple shipments are reported in tables 2 and 3. In the two alternative estimations of the model, the "expected delay" and the "expected cost of delay" were used respectively as the variable for the variability of transit time. However, there is very little difference in the results between two specifications of the model. In both cases, the freight-charge coefficients have expected signs and are highly significant. The variability of transit time coefficients also have expected signs and are significant at the 5% level using the normal approximation.

The rail transit time coefficient has a positive sign and is significant at the 5% level, indicating that buyers are indeed substituting transit time for the time in inventory. The truck transit time coefficient is not statistically significant. The lack of significance is probably due to specification bias, i.e., some variables affecting model choice were not included

[3] This expression is readily obtained in the binary case by taking the total derivative of the logit equation, holding all X but X_i constant. The logit equation and its derivative are

$$p/(1-p) = e^{\alpha + \Sigma \beta_j X_j}$$

$$dp - (1-p)^2 \beta_i dX_i \, e^{\alpha + \Sigma \beta_j X_j} = 0.$$

Solving for the elasticity yields $(dp\, X_i)/(dX_i\, p) = \beta_i X_i(1-p)$. The estimated point elasticity of Q with respect to X_i is then $\beta_i \overline{X}_i(1-\overline{p})$, where $\overline{X}_i$ is the sample mean of X_i and $\overline{p}$ is the observed proportion of the shipments using the mode in question.

[4] The use of the normal approximation is justified by the large number of observations (516).

Table 2. Elasticities and Cross Elasticities of Demand for Rail and Truck Transportation of Apples (Transit Time = Expected Delay)

Variable	Coefficient	*t*-ratio	Elasticity or Cross Elasticity for Rail Service	Elasticity or Cross Elasticity for Truck Service
Rail freight charges	−5.9088	6.7364	−12.5702	3.5455
Truck freight charges	4.7388	6.7960	10.0454	−6.4396
Rail transit time	0.7106	2.1924	2.7252	−0.7686
Truck transit time	−0.4670	0.7559	−1.1759	0.3317
Expected delay—rail	−0.7682	2.7636	−0.5272	0.1811
Expected delay—truck	9.9354	1.6899	0.1778	−0.0501
Constant	0.4460	0.2637	—	—

in the model. For example, truck transportation may have been chosen because it is more flexible. Unlike railroads, truckers are not constrained either to the scheduling or to fixed point pickup and delivery of trains. The buyer may have been willing to pay higher charges for this flexibility.

There also may be a feedback effect between choice of transport mode and size of shipment; the quantity a buyer wishes to ship may determine the mode and the mode chosen may limit the size of the shipment. Clearly, the capacity of a rail car is greater than that of a truck. The efficiency of trucks for transportation of small lots, however, may not be reflected in freight charge differences.

The overall explanatory power of the model is still satisfactory. The χ^2 is equal to 290.19, again way above the critical value of 18.55.

Conclusions

The purpose of the research effort, the results of which are reported in this paper, was to use the logit model to estimate the elasticities and cross elasticities for freight transport services. The model was applied to a sample of cherry shipments and a sample of apple shipments moving long distances to their markets.

The results for cherry shipments are rather encouraging. All estimated coefficients had a priori expected signs and were highly significant. Overall, the performance of the model in explaining modal choices was highly satisfactory.

The results for apple shipments are less satisfactory. It is difficult to provide a satisfactory explanation for the positive sign of the rail transit time coefficient and statistically insignificant truck transit time coefficient. Incomplete specification of the model is one possible explanation. The missing interrelationship between inventory and transport mode decisions is another. Inventory considerations as well as the decision where to buy may be closely interrelated with the choice of the transport mode.

Testing of this hypothesis would require development of the model that would cover the complete decision process rather than concentrating on the choice of the transport mode alone. While such a model could be developed, its testing would require considerable data collection effort. However, before this research effort is undertaken, it may be advisable to apply the logit model to shipments of other commodities. After all, by their nature, the estimates obtained in this study are specific, for they are functions of the sample

Table 3. Elasticities and Cross Elasticities of Demand for Rail and Truck Transportation of Applies (Transit Time = Expected Cost of Delay)

Variable	Coefficient	*t*-ratio	Elasticity or Cross Elasticity for Rail Service	Elasticity or Cross Elasticity for Truck Service
Rail freight charges	−5.8368	6.8416	−12.4170	3.5022
Truck freight charges	4.6846	6.7014	9.9308	−2.8010
Rail transit time	0.7274	2.2614	2.7896	−0.7868
Truck transit time	−0.4790	0.7801	−1.2063	0.3402
Expected cost of delay—rail	−0.3030	2.6895	−0.4413	0.1245
Expected cost of delay—truck	0.5240	1.9315	0.1697	−0.0479
Constant	−0.6632	0.3979	—	—

data. Repeated applications of the model would provide a further evaluation and guidance for the future research work.

Appendix

Nature and Sources of Data

The main source of data on cherry shipments was the survey conducted by the Washington State Department of Agriculture. The survey covered the 1972 shipping season, which started on June 13 and continued through August 2, a total of fifty-one days.

In the survey a cross section of shippers was selected, and all shipments of those selected were included in the sample. The survey supplied information on 1,374 shipments accounting for 9,455 tons or approximately one-fourth of the crop grown in the three Northwest states.

The total sample, however, could not be used for estimation of the model. Shipments lacking information on one or more variables were omitted from the sample. First, age of pack was not reported for 536 shipments. Second, rail freight rates were not available to destinations west of Denver since all shipments move by truck. Third, shipments to Canadian destinations had to be excluded because of the difficulties in obtaining truck freight charges. As a result, the subsample used for estimation of the model contained 516 observations. The distribution of shipments by transport mode in the subsample was as follows. There were 305 shipments by rail (59.1%) and 211 shipments by truck (40.9%). The survey provided no information on freight charges. The truck freight charges were obtained from shippers and truckers, while the rail freight charges were supplied by the Burlington Northern, Inc.

The main source of data on apple shipments was provided by the survey conducted by the Department of Agricultural Economics, Washington State University. Although the survey was conducted in 1974, it covered the 1972 shipping season. The selection of 1972 shipping season was dictated by the shortages of rail and truck capacity beginning with the "fuel crisis" of 1973. In later years, choice of the transport mode was dictated by first availability of equipment. This, in turn, violates the basic assumption of the model that a decisionmaker has a choice of alternative modes.

For the survey apple shippers located in the Yakima, Washington, area were stratified by size, and two large, three medium, and two small shippers were drawn randomly. Then every tenth shipment was selected from their records.

This procedure produced a total sample of 821 observations. Again shipments to destinations west of Denver and shipments to buyers who did not respond to our

supplementary survey of buyers described above were excluded. The subsample used for estimation of the model included 577 shipments. The distribution of shipments by transport mode in the subsample was as follows. There were 127 shipments by rail (22%) and 450 shipments by truck (78%). The truck freight charges were obtained from shippers and truckers and the rail freight charges were supplied by the Burlington Northern, Inc.

Grain Marketing and Transportation Interdependencies: A National Model

Jerry A. Fedeler and Earl O. Heady

Ten specifications of a linear programming model are developed to jointly select the least cost locations of grain production and interregional grain transportation in the United States. Analyses are based on 1980 demand projections for wheat, soybeans, and feed grains. Seven model options represent alternative transportation systems and include alternative cost estimates for railroad and barge transportation. Three other options are specified to analyze interdependencies between grain exports and transportation. Results suggest that choice of transportation mode and grain flows are sensitive to transportation cost changes and the distribution of exports among ports but the location of grain production is not.

Key words: barges, grain exports, grain production, grain transportation, railroads, trucks.

Grain exports at unprecedented levels in 1972 placed severe pressures on the grain transportation network. The event indicated the dependence of farmers, grain elevator managers, processors, exporters, and other groups on the transportation system. In 1975 there are rumors of large U.S. grain exports. Hence, the grain transportation system may face comparable pressures in the future.

The widespread transportation shortages in 1972 vividly illustrated that grain transportation depends on a national system, even though it is comprised of smaller, interlinked components. This national network can be viewed as an interregional competition system, but few researchers have empirically developed such systems except for studies of industrial plant location.[1] Too frequently only part of the entire national system has been considered in analyses that omit major routes, modes, grains, or areas. The most comprehensive of earlier models are those by Leath and Blakley and the associated models by Schnake and Franzmann. Their models are national, include wheat, feed grains, and soybeans, and utilize rail, water, and highway transportation. Schnake and Franzmann compare a cost-of-service transportation rate structure with actual rates. They summarize national transportation costs but unfortunately do not give either cost or traffic volume by transportation mode.

This paper describes the methods and results of an interregional grain transportation study within the United States for 1980. The emphasis is on choice among transportation modes, grain movements, and production regions.[2] The analysis projects regional demands and determines the least cost configuration of transportation and production under six alternative transportation systems, two alternative distributions of exports among port regions, and one alternative level of exports (table 1).[3]

Grains included are wheat, soybeans, corn, oats, barley, and grain sorghums; the last four are aggregated into one commodity, feed grains, on the basis of their feed values. In addition to these grains, cotton is included because it competes with grains for cropland

Journal Paper No. J-8133 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa. Project No. 1885.

[1] Among the interregional studies are those by Free; Schnake and Franzmann; Leath and Blakely; and Wright. These are all national in scope, have fixed regional grain supplies, and emphasize the location of industrial grain-processing plants.

[2] Past studies concentrating on the location of grain production have not considered changes in transportation activities. Several examples of these models are in Heady, Mayer, and Madsen.

[3] Transportation costs in the model are designed to represent transportation operators' costs, not the market price of transportation services, plus grain elevator loading and unloading costs. Therefore, using 1972 as the base year does not introduce unusual costs stemming from abnormal marketings in 1972.

Table 1. Alternative Model Specifications

Option[a]	
1	The base model (has an estimated 1972 interregional transportation cost structure with demands and yields projected for normal or average conditions for 1980 based on past trends)
2	A rail system with shipments in 50-car units (is incorporated to represent a transportation network including a multicar system, i.e., a rail system with large individual shipments)
3	A 10% increase in all rail costs
4	A 20% increase in all rail costs
5	A 10% increase in all barge costs
6	A 20% increase in all barge costs
7	An alternative single-car rail transport system (reducing the variable and increasing the fixed cost of rail transportation)
8	A reassignment of 10% of the Gulf export demands to Seattle (to analyze redistribution of the traditional demands for exports among ports at the Gulf and the Northwest coast)
9	A reassignment of 25% of the Gulf export demands to Seattle
10[b]	A 25% increase in all grain exports

[a] Options 2 through 10 are identical to option 1, except for the changes indicated in the table.
[b] Additional exports in option 10 are assumed to be exported as unprocessed, whole grain, and the percentage distribution among port regions is the same as for option 1.

and cottonseed is a major substitute for soybeans.

Methods and Procedure

Domestic and export demands are first projected to 1980 for each crop.[4] A linear programming model determines the least cost transportation modes, grain shipments, and production location for each crop. Seventy-eight domestic and export demand regions and 152 producing regions are delineated for the forty-eight contiguous states.

The Model

The variables in the linear programming model represent interregional grain transportation processes and regional grain and cotton production activities.[5] The objective function is

$$APTC = \sum_k \sum_i C_i^k X_i^k + \sum_k \sum_i \sum_j \sum_t P_{ijt}^k T_{ijt}^k,$$

where $APTC$ = annual production and transportation costs, i = producing region index, k = crop index, C_i^k = all costs, except land, of producing crop k in region i, t = time period index, X_i^k = the number of acres of crop k produced in region i, P_{ijt}^k = the cost of transporting one ton of crop k in time period t from producing region i to consuming region j, and T_{ijt}^k = the number of tons of crop k transported in time period t from producing region i to consuming region j. Annual production and transportation costs are minimized subject to regional land constraints identified in a previous study (Heady, Mayer, and Madsen, p. 115).[6] In addition, acreage bounds are specified as a substitute for other constraints (including seasonality of labor, risk, conservation practices, and disease control) that discourage crop production specialization. These bounds are not totally restrictive but permit 1980 crop acreages to range at least from 20% below to 20% above 1969 actual acreages, except upper limits on soybean acreages are restricted to 50% of the available land or 1969 actual acreages, whichever is larger (Fedeler, Heady, and Koo, pp. 60–61).[7] The amount of each crop shipped from a region is constrained to be no more than the regional production.

Feed grains, soybeans, and wheat shipped into a consuming region during each time period are required to be no less than the consuming region's corresponding demand. Annual demands for feed grains and soybeans are allocated to two periods, December through March and April through November, because the Missouri River, the Upper Mississippi River, and the Great Lakes are not navigable in winter. Regional wheat demands remain on an annual basis to lower computational costs.[8] The model requires cotton production to satisfy a national cotton lint demand and the

[4] All demands estimated are fixed-point estimates of the quantity demanded, given the underlying parameters of the projections.

[5] The crop yields and production costs are those for the typical farm structure described in detail elsewhere (Sonka, pp. 79–116).

[6] In the earlier model, the major grain-producing areas are divided into 150 producing regions by aggregating counties with relatively homogeneous production characteristics. The two additional regions, 151 and 152, stem from dividing region 71 of the former study into three regions, so that one of them corresponds to the area intensively analyzed elsewhere (Baumel et al.).

[7] Because nearly all available land is utilized in option 10, the upper bounds for feed grains and wheat in that option are adjusted upward for some regions so that the sum of the lower limits for cotton and soybeans plus the upper limits for feed grains and wheat is at least as great as the total land available in each region. A comprehensive analysis shows that very few of these are significantly restrictive (Fedeler, Heady, and Koo, pp. 84–88).

[8] Preferably, two demand periods would be used for wheat; however, this simplification may not be overly restrictive because timing of the wheat harvest readily permits shipments by water after harvest and before winter, allowing it to be stored near either origins or destinations, and water transportation is relatively less important for wheat. In 1972, for example, the quantity of wheat shipped by rail was 7.2 times that shipped by water whereas the ratio was 1.2 for soybeans and 2.8 for feed grains (Fedeler, Heady, and Koo, pp. 174, 178).

resulting cottonseed in excess of seed requirements is used to partially satisfy an aggregate demand for soybean and cottonseed meal. The aggregation is based on their relative feed values and the balance of the aggregate demand is met by soybeans. The cottonseed meal is regionally distributed so that it does not distort the regional distribution of demands by soybean processors.

Demands

Total national demands for 1980 are projected on the basis of 226.9 million U.S. population. Demands for livestock feed are derived from projected per capita demands for livestock products (beef, pork, broilers, sheep, turkey, milk, and eggs) adjusted for net foreign trade and direct grain demands for horses, mules, and other livestock. Demand projections include industrial uses of grain such as cereal, dry processing, wet processing, flour, alcohol, malt, etc. Per capita demands are based on commodity price indexes, real income per capita, and time. Two levels of grain exports are considered to surmount unpredictable events surrounding changes in foreign trade policy. For options 1 through 9, exports are 27.5 million tons of corn equivalent feed grains, 22.4 million tons of wheat and wheat flour equivalent, 31.2 million tons of soybeans and soybean meal equivalent, and 2.1 million bales of cotton lint. Feedgrain, wheat, and soybean exports are 25% greater in option 10.[9]

Transportation Costs

The model utilizes transportation costs between producing and consuming regions by crop and time period. Transportation costs in option 1 are for rail movements in single hopper cars; highway movements in five-axle, tractor-semitrailer trucks; barge movements in 195′ × 35′ covered hopper barges, except on the Columbia and Snake rivers where costs are estimated for 250′ × 42′ barges; and ship movements on the Great Lakes. Combinations of transportation modes are used when they are the least costly method. In option 1, single-car rail costs for a route are $RC_g = \sum_{i=1}^{4} k_{gi}M_i + 1/2(T_{go} + T_{gd})$, where RC_g is the rail cost for grain g, k_{gi} is the mileage coefficient for grain g and rail cost territory i, M_i is mileage in territory i, T_{go} is terminal cost for the origin, and T_{gd} is terminal cost for the destination. Territories for computing rail costs are the Official (including New England), Southern, Western (excluding Mountain Pacific), and Mountain Pacific. Values for k_{gi}, T_{go}, and T_{gd} for 1972 are computed by inflating corresponding published values 24% for price and wage increases (Interstate Commerce Commission, July 1972). Published variable costs are used because they are broadly defined as "costs, which over the long-run period, . . . have been found to be variable with traffic changes" (Interstate Commerce Commission, July 1972, p. 4) and fixed costs are allocated arbitrarily on the basis of ton-miles, placing an excessively large burden on heavy cargo like grain.

The fifty-car costs for option 2 are derived by adjusting single-car costs using the procedure developed in the study by Baumel et al. because there are no comparable Interstate Commerce Commission (ICC) published costs for multicar shipments. The alternative rail costs in option 7 have 50% greater terminal costs and 10% lower mileage costs than the single-car costs in option 1. This option is included to show the effects of biases some industry personnel claim are built into the published costs.

Barging costs for a given route are $BC_g = \sum_{i=1}^{n} (t_i^1 T_g + t_i^e) M_i + K$, where BC_g is barge load cost for grain g, n is the number of river sections traveled, t_i^1 is towing cost per ton-mile for a loaded barge for river section i, T_g is tons (actual or minimum required for the towing charge) of grain g, t_i^e is return trip towing cost per mile for an empty barge for river section i, M_i is miles traveled on river section i, and K is the sum of other barging costs. Included in K are capital ownership cost, insurance, maintenance, repair, cleaning, administration, overhead, and tax costs for the barge, and total round trip switching, fleeting, and harbor costs. Most of the cost variables are unique for specific river sections, origins, and destinations and are in Fedeler, Heady, and Koo.[10] Water systems included are the Mississippi River and its tributaries, the Gulf of Mexico, the Warrior-Tombigbee river system, and the Columbia and Snake rivers. The estimated cost of shipping from Duluth to Buf-

[9] The derivation of demands by regions and time periods and additional details of the demand projections can be found in Fedeler, Heady, and Koo.

[10] Estimates for water transportation costs benefited substantially from data supplied by industry representatives.

falo is 15¢ per bushel. Other potential Great Lakes shipping routes were eliminated prior to solving the linear program because of high cost vis-à-vis other transport modes.

Trucking costs for a given route are $TC = 1.6 \sum_{i=1}^{8} (C_v^h H + C_v^m M)\, d_i F_i + 2/3 C_v^h$, where TC is truckload cost, C_v^h is the hourly cost, H is hours per one-way trip, C_v^m is mileage cost, M is one-way mileage, d_i is percentage of miles in truck cost region i, and F_i is an adjustment factor for region i. The costs of fuel, oil, tires, maintenance, and repairs are allocated to distance and the capital cost of ownership, license fees, insurance, highway use tax, overhead, and driver's wages are allocated to time. For the Midwest, C_v^h is \$8.70, C_v^m is 11.035¢, and F_i is 1. For seven other regions (New England, Middle Atlantic, Central, Southern, Southwestern, Rocky Mountain, and Pacific Coast), F_i is the ratio of the region's to the Midwest's line haul costs for moving 20,000 to 29,999 pounds 100 to 124 miles (Interstate Commerce Commission, May 1972). The coefficient 1.6 accounts for an assumed backhaul for 40% of the return trips and the last term represents the estimated truck (not grain elevator) cost of forty minutes per trip for loading and unloading.

Transportation cost coefficients in the objective function of the model are the sum of the carriers' costs and elevator loading and unloading costs adopted from table 3 in Schienbein and Vosloh. Transportation costs for feed grains originating in a producing region are the weighted averages for the individual grains. The weights are the relative tonnage of each grain sold from farms for the state containing the producing region.

Results and Implications

The model's solutions provide transportation costs and interregional shipments by grain and transportation mode for each option. National results are emphasized because they depict overall differences among options and have national implications, but this does not detract from the importance of results for localities.

Transportation

The quantities of grain hauled interregionally by individual transportation modes vary substantially among the options (table 2).[11] Multimodal hauls are either rail-water or truck-water combinations. Rail-water shipments are surprisingly large and exceed truck-water tonnages in options 2, 5, 6, and 10. In option 1, 6.3 million tons are transported by rail-water and 7.0 million tons by truck-water. Twenty-one percent shipped by water in option 1 is moved in conjunction with rail. Current multimodal data are not available but most are undoubtedly truck-water. In reality, obtaining significant increases in rail-water shipments through normal rate adjustments is question-

[11] In the model, all grain is shipped from the producing regions to consuming regions. No transportation cost is charged for intraregional shipments, i.e., transfers of grain from a producing region to the consuming region containing part or all of the producing region. This is justified because much grain is utilized locally, including on farms where grown. Consequently, interregional shipments are defined as grain moved out of the consuming region where produced.

Table 2. Interregional Grain Shipments

Option	Rail (1,000 tons)	Water[a] (1,000 tons)	Truck	Multi-modal	Total[b]
1. Single-car	116,741	30,280	6,975	13,266	140,730
2. 50-car	121,049	24,372	2,789	7,070	141,140
3. 10% rail	113,012	33,397	11,405	17,385	140,429
4. 20% rail	107,976	38,771	14,752	20,914	140,585
5. 10% barge	120,556	26,339	2,991	9,223	140,663
6. 20% barge	121,859	24,255	2,568	7,884	140,798
7. Alternative single-car	111,705	30,490	11,418	12,917	140,696
8. 10% Gulf-Seattle	118,364	26,756	5,425	9,921	140,624
9. 25% Gulf-Seattle	120,708	22,390	4,519	6,803	140,814
10. 25% export	127,954	35,361	8,451	18,089	153,677

[a] Ships are assumed to be used for the Great Lakes and the 1,000 tons they haul are 199 in option 2, none in option 7, 801 in option 10, and 883 in options 1, 3, 4, 5, 6, 8, and 9. Barges carry all other water shipments.
[b] Total shipments equal the sum of rail, water, and truck less multimodal shipments because a ton transported by a combination of modes is reported for each individual mode.

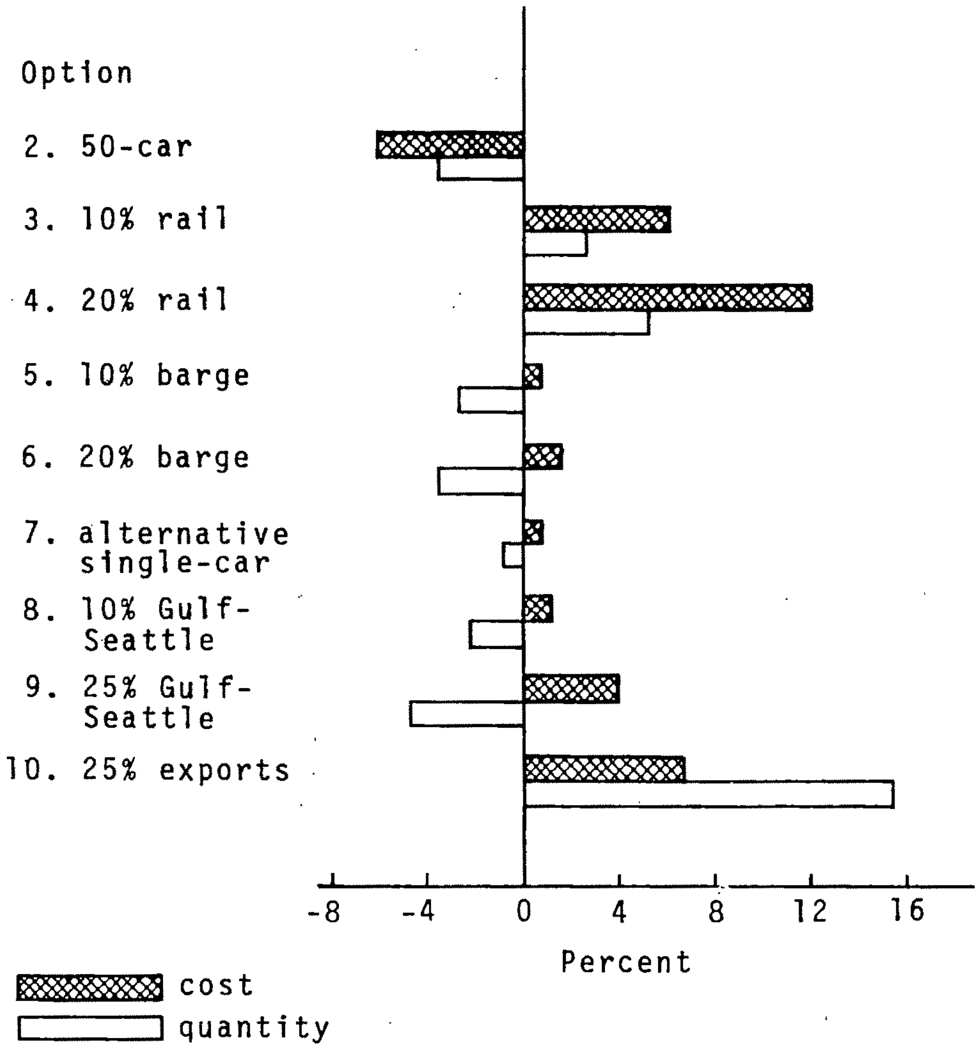

Figure 1. Percentage change from option 1 in interregional grain transportation costs and sum of rail, water, and truck shipments

able because it would likely be unprofitable for individual carriers. Truckers are reluctant to turn over to railroads hauls from producing areas to barging points and railroads prefer to capture an entire haul all the way to final destination rather than surrender part of it to barges. Nevertheless, for least cost transportation, the results suggest policymakers should review possibilities for increasing rail-barge shipments.

The 6.1% cost decrease in option 2 (figure 1) is equivalent to 56¢ per ton of grain hauled by rail. Because larger volumes would be gathered together at fewer points, assembling them for shipment would likely be more expensive for fifty-car than for single-car rail shipments. But the 6.1% cost reduction of option 2 would more than offset the added assembly cost in localities with relatively heavy outbound shipments per unit area. This conclusion is supported by an analysis of a region by Baumel et al.

Total transportation costs are substantially affected by changes in rail costs but affected little by barge costs changes (figure 1). The largest cost increases, excluding option 10, result from the 10% and 20% increases in rail costs, options 3 and 4. For each 10% increase in rail costs, total transportation costs increase approximately 0.6% for both options 3 and 4. Barging cost increases, options 5 and 6, result in higher transportation costs (figure 1), fewer barge and truck shipments, and more rail shipments (table 2) than in option 1. Two re-

Table 3. Summary of Grain Traffic

	Rail		Inland Waterways	
Year	(Million tons)	(Billion ton-miles)	(Million tons)	(Billion ton-miles)
1971	97	42	24.9	22.7
1972	105	46	32.5	35.4
1973	131	57	32.6	37.1
1980 option 1	117	87	30.3	36.4
1980 option 10	128	91	35.4	43.2

Note: Col. 1, 1971–73, obtained from Interstate Commerce Commission, *Freight Commodity Statistics Class I Railroads*. Col. 2, 1971–73, estimated by multiplying the number of tons by the average haul per ton for grain as reported by the U.S. Dep. of Transportation. Cols. 3 and 4, 1971–73, obtained from U.S. Corps of Engineers.

sults regarding rail and barge cost increases deserve further comment. First, transportation costs, vis-à-vis tons hauled, increase more for rail than for barge cost increases. In option 1, tons hauled by rail are 3.97 times the tons shipped by barge but the increase in transportation costs is 7.11 times larger for a 20% increase in rail costs than for an equal increase in barge costs. Second, grain switches more readily from rail to barge when rail costs increase than from barge to rail when barge costs increase, i.e., both the quantity railroaded and the quantity barged are more responsive to rail cost changes than to equal percentage barge cost changes. When rail costs are increased 20%, the quantity barged increases 28.9%, but when barge costs are increased 20%, the quantity barged decreases only 20.5%. These results occur because multimodal shipments are more common with barges than with rail. The percentage of all tons barged that are part of multimodal shipments is 44 in option 1, 35 in option 4, and 33 in option 6. The comparable percentages for rail are 5 in option 1, 8 in option 4, and 3 in option 6. For a multimodal shipment, when the cost for one mode changes the intermodal transfer costs, the costs associated with other modes remain unchanged. The model selects methods of transportation on the basis of cost for entire routes. Consequently, the impacts of changes in barge costs are smaller than for equal percentage changes in rail costs.

Grain elevator loading and unloading costs among options 1 through 9 range from $239 million in option 2 to $251 million in option 4. The ranking of the options by elevator costs is very similar to their ranking by multimodal shipments (table 2) because of the elevator costs for intermodal transfers. Elevator costs as a percentage of total interregional transportation costs range from 19.9 in option 4 to 22.5 in option 2, and the average for all options is 21.2. Elevator costs are an important part of transportation costs and should be included in grain marketing decisions. If a program for grain reserves is adopted, decisions pertaining to their storage location should include loading and unloading costs.

Compared to tons transported in 1972 and 1973, rail data for the model (table 3) are biased downward because they exclude intraregional shipments and the division of a haul into two shorter ones through the unloading and later reloading of rail cars. Also, shipments occurring because of daily fluctuations, imperfect coordination, and other real world frictions among markets are left out.[12] Taking this bias into account it is likely that tons hauled by rail in 1980 will be at least 20% greater than the interregional shipments resulting from the model. The need for expanded railroad capacity is likely to grow even more rapidly when it is expressed in ton-miles than in tons (table 3). To the extent these results can be used to project the demand for rail, it can be concluded that by 1980 rail capacity will need to be even greater than it was in 1973. If exports are as large as in option 10, as many as 154 million tons (17% more than in 1973) could be railroaded.

Internal grain shipments by water in 1961 were 10.3 million tons and 9.5 billion ton-miles (U.S. Corps of Engineers). By 1972 they had grown to 32.5 million tons and 35.4 billion ton-miles (table 3). Results for water, vis-à-vis rail, are more comparable to reality because grain seldom moves intraregionally by water and rarely is unloaded from and reloaded onto barges. Under assumptions of option 1, it can

[12] If rail costs in the model are lower than actual rates, the model may overestimate interregional grain traffic. But the small variation in total tons shipped interregionally among the first nine options suggests that this bias towards overestimation is minimal.

be concluded that water shipments will stabilize near current levels. But results from options 8, 9, and 10 show that water shipments are closely related to exports. Decisions pertaining to the development of river navigation should carefully consider the level and port distribution of exports.

Interregional Grain Flows

The variation in total interregional shipments among options 1 through 9 is small; the ratio of the greatest, option 2, to the smallest, option 3, is only 1.005. The magnitude of total flows for individual options have limited significance because they depend on the delineation of regions. But the small variation among the options shows that moderate changes in the transportation cost structure and distribution of exports among ports do not significantly change the division between interregional and intraregional shipments. The variation might have been greater if the model had included the choice of location for grain-processing plants. The stability in the location of final demand, however, probably would be similar to that of production unless there were changes in the relationship between the transportation costs for processor inputs (whole grain) and their products.

The constancy of the total flows belies, however, the extent of changes in individual flows. Among the options, the net change in the total number of flows (329 in option 1) is small, but the set of flows selected varies substantially. The complete removal and addition of flows reflects essentially all changes because the magnitudes of flows for the same route in two options are with very few exceptions identical. Comparisons of option 1 with the other options show that option 9 has the greatest change in individual flows with a net increase of only 19 flows resulting from the addition of 114 new flows and the removal of 95 flows that were in option 1. Option 5 has the fewest changes with a net addition of 8 flows resulting from the addition of 38 new flows and the removal of 30 flows that are in option 1. These results suggest that transportation cost and export demand changes are likely to substantially disrupt the configuration of interregional grain flows, while their total quantity remains stable. This is particularly relevant for terminal grain elevators, warehouses, and wholesalers. A good location for grain traders may be undesirable under a different transportation cost structure. Although the flow of grain through an elevator may be stable, the location of those who buy from or sell to the elevator may be sensitive to transportation and export changes.

Total grain exports in option 10 are 20.3 million tons more than in option 1 but interregional flows increase only 12.9 million tons. If production and grain markets are given time to adjust to higher export levels, the increase in interregional transportation requirements is significantly less than the increase in exports.

Production

The variation in national yields, acres utilized, and production costs (excluding returns to land) is small among options 1 through 9. Higher export levels of option 10 require more production (table 4), which is possible within the model by utilizing more land at somewhat lower yields.

Feed-grain, soybean, and wheat production for options 2 through 9 are the same as option 1 in at least 146 of the 152 producing areas. Regional cotton production is identical among options 1 through 9. Complementary to the location of production is the geographical distribution of available land not used for crops. Land not used for crops in option 1 is shown in figure 2. Again it is more important to emphasize the constancy in location of unused land among the options than its location for any single option. The location of available cropland not used for crops in option 1 remains nearly the same for options 2 through 9. The greatest changes in land utilization occur when rail costs are increased 20%, option 4. In that option the area of unused cropland in North Dakota increases 1,066,800 acres. The corresponding increase in cropland utilization that offsets the decline in North Dakota is scattered among Georgia, Ohio, Minnesota, Kansas, and Oklahoma. This million-acre shift represents less than 4% of the 28.3 million unused acres in option 1. Increasing rail

[b] Figures obtained from the U.S. Dep. of Agriculture.

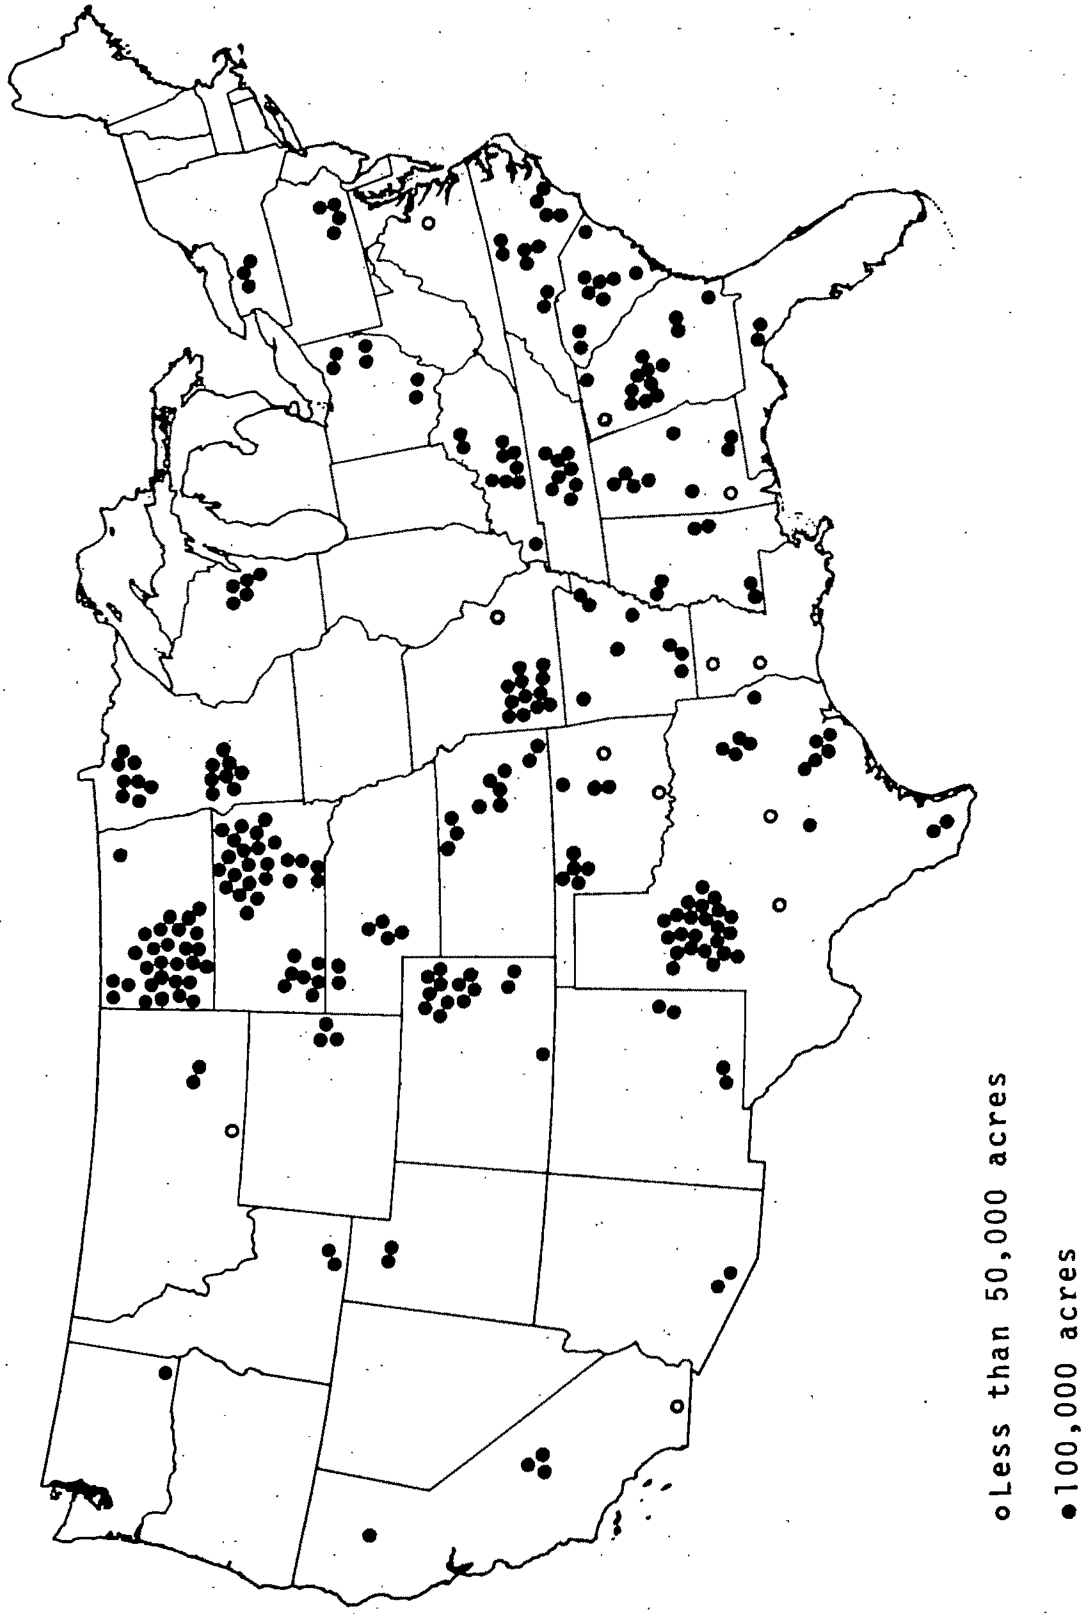

Figure 2. The location of cropland not used for crops in option 1

costs 10%, option 3, results in a shift in land utilization similar to that of option 4, but the extent of the shift is smaller; unused cropland in North Dakota increases 683,187 acres. In option 9, 753,016 more crop acres in western Minnesota are used and 424,780 acres in Ohio, Kansas, and Texas go unused compared to option 1. At national average yields, this shift represents less than 8% of the land needed to produce the additional demand at Seattle.

Total crop production costs did not differ significantly among the first nine options. These results suggest that moderate changes in transportation costs similar to those of options 2 through 7 would not have significant impacts on national yields, land use, or production costs. Currently, a major transportation policy issue concerns the financial condition of railroads. Our results suggest that 10% or 20% rail rate increases would have minimal effects on yields, land use, and nonland production costs. Such a change would not significantly shift the location of grain production from, for example, the Corn Belt to the Southeast. Similarly, if user charges equivalent to 10% to 20% of barging costs were imposed on barge traffic, there would be no significant shifts in location of grain production from the Corn Belt to the Delta States, even though substantial quantities of grain are now barged from the Corn Belt to Gulf ports.

Shifts in the location of demand, such as from the Gulf ports to Seattle in options 8 and 9 also result in very small changes in yields, land use, and production costs. This shift is only one of several possible shifts in the distribution of exports among port regions; however, it is probably one of the more likely and one that would result in more dramatic effects. Also, it is likely to occur to some degree because (*a*) ports in the Northwest have deep water, (*b*) more exports may go to Asian countries because of their growing population and opening of trade, (*c*) the Panama Canal cannot accommodate the very large ships, (*d*) multicar rail shipments can be used to deliver grain to ports in the Northwest, and (*e*) the Gulf ports are congested. Other possible shifts in the distribution of export demands could arise from the inability of large ships to sail the St. Lawrence Seaway, the development of deepwater ports off the Atlantic coast, and further expansion of the Gulf ports such as at Mobile.

Prices

Shadow prices computed prior to transportation in the model are called "county elevator prices" because they represent supply prices at producing regions. Shadow prices after transportation are called "consuming region prices" because they represent supply prices at points of processing, feeding, or export (table 5).[13] Prices for any one option depend on the nonland production costs, demands, yields, land constraints, crop activity bounds, transportation costs, and the structure of the model. Consequently, the important analysis is the variation in prices among the options. Then, for example, even if the demand projec-

[13] If intraregional transportation costs were included, the price changes, especially at the consuming regions, would be somewhat greater.

[a] Corn equivalent units.

tions for 1980 prove to be incorrect, analyses of results from the model will still be relevant.

Most of the effects of the differences among options 1 through 9 are absorbed by price changes and returns to resources rather than the relocation of grain production. Consequently, policymakers should expect changes in relative rates among transportation modes to be reflected largely in price changes, while the stability of the location of grain production is maintained. This conclusion is reached by comparing the variation in country elevator prices and production costs among the options and recalling the stability of the location of production discussed earlier. The percentage differences between the high and low country elevator prices among options 1 through 9 for feed grains, soybeans, and wheat are twelve to fifteen times greater than the percentage differences between the high and low nonland production costs. Thus the results suggest that transportation costs and export demand shifts among ports have a much larger impact on prices than on yields, location, and nonland production costs.

For feed grains, soybeans, and wheat, national average country elevator prices increase and the average consuming region prices decline when multicar, option 2, versus single-car, option 1, rail shipments are used (table 5). This suggests that multicar systems similar to the one in option 2 have the potential of increasing farm prices and lowering consumer food costs. In option 2, fifty-car rail units are used for all rail shipments except those that are a part of multimodal shipments. Some of the shipments hauled solely by rail in option 2 are in reality too small to support a fifty-car unit system. Thus, it is unlikely that a multicar system similar to the one in option 2 will be universally developed. The development of a multicar system would tend to increase grain prices and returns to resources in those regions that could effectively adopt it, i.e., those regions with intense production and a large volume of outbound shipments. It would have the opposite effect in regions of sparse production and small exports. Consequently, the development of an effective multicar system will not be beneficial to all localities, even though it may be nationally beneficial. The regions that adopt an effective multicar system will require a reorganization of the assembly of grain for rail shipment, which has income and employment implications for many rural towns. There has been a tendency for railroads to only utilize multicar shipments to compete with barges. But multicar shipments should be considered for other routes, such as shipments from the Corn Belt to the Northwest, because they may reduce total transportation costs and thereby improve farm and consumer prices.

Greater rail and barge costs in options 3 through 6 increase prices at both country elevators and consuming regions compared to option 1 (table 5). The consuming region prices increase more than country elevator prices except for wheat with higher barge costs, options 5 and 6. This suggests, given fixed quantities demanded, the consuming region prices tend to absorb the majority of the price changes that result from rail and barge cost increases. If the assumption of fixed quantities demanded were relaxed, the impacts would result in both price and quantity changes. The more elastic the demands, the greater the effects on the quantities demanded. Price changes for the alternate single-car option, compared to option 1, depend on the average distance grain is hauled. Country elevator and consuming region feed-grain prices are unchanged because on the average they are hauled medium to long distances. But the country elevator-consuming region price spread increases for soybeans and wheat because their average haul is relatively short. The 10% shift in export demands from the Gulf to Seattle compared to option 1 results in higher country elevator and consuming region prices for feed grains and soybeans, but these prices are lower for a 25% shift, option 9. Country elevator and consuming region wheat prices are higher in options 8 and 9 than in option 1 because a large volume of wheat is grown near and exported from the Northwest. The differences in prices among the first nine options seem small, but they are not meager in terms of total national impact. Total feed-grain, soybean, and wheat production with the base level of exports is projected to be 11.2 billion combined bushels in 1980. A 1¢ per bushel change would thus have a national value of $112 million.

Conclusions

The results of the analysis provide implications for certain national policies. The analysis utilizes costs of providing transportation rather than transportation rates, but neverthe-

less the results can be applied to similar actual rate changes.[14] Among innovations and policy changes that could have effects similar to those that result from the options of the model are adoption of a multicar rail system on a broad scale, higher rail rates to strengthen the financial position of railroads, and the implementation of fees for recouping the capital investments in the inland waterways.

Specific variations in transportation costs produce substantial changes in the quantities and directions of individual interregional grain flows, but only small changes in the location of production and in the total of all interregional flows. Transportation cost changes have a much larger impact on prices and returns to resources than on the location of production. The effects on prices and returns to resources are not uniform among the regions; both their magnitudes and directions vary. Hence, analyses of specific transportation policies should concentrate on regional income and price effects rather than on the location of production.

Attention has focused on shifting exports from the Gulf ports to ports on the Northwest coast. If this shift occurs, there is likely to be a substantial change in the pattern of grain flows and some changes in the production location of particular crops, but cropland that is idle before the shift will likely remain idle. The greater the increases in exports and the shifting of the demand for exports to the Northwest, the greater the need for additional rail capacity. The quantity of grain carried on the inland waterways will stabilize near present levels, unless there is a substantial change in export levels or the ports from which it is exported.

The analysis of fuel costs is not specifically incorporated into the model, however, some imperfect comparisons between higher fuel costs and the model options can be made. For example, the doubling of fuel costs in 1973 through 1974 is similar to option 5 because introducing such a fuel price change into the model increases barge and truck costs about 10% more than rail costs increase (Fedeler, Heady, and Koo, pp. 182–85). A change in the choice of transportation mode is likely to be one of the major effects of higher fuel costs with regard to grain traffic. Railroads are likely to increase their share of the traffic because higher fuel prices induce greater percentage increases in total costs for both barges and trucks than for railroads (Fedeler, Heady, and Koo, pp. 179–82).[15]

Relationships between the grain and transportation industries need further exploration. Both industries contain large, long-term investments. The research summarized demonstrates their interdependence. Investments appropriate in one industry could readily become unprofitable with changes in the other. The dynamics of world trade, grain prices, fuel supplies and costs, etc., suggest the interdependence of the two industries is especially important at this time.

Modeling the Optimal Location of the Cattle Feeding Industry

Donald L. Byrkett, Richard A. Miller, and E. Paul Taiganides

A variety of interregional linear programming models have been used to study the optimal location of the cattle feeding industry. An analysis is performed to determine which factors are most influential in determining feedlot location and thus need to be included in these models. In addition to traditional factors, consideration is given to the effects of region definition and regional land use patterns. Results indicate the importance of feeders, grain, and land use patterns. The implications of these results in the analysis of future trends in feedlot location is discussed.

Key words: cattle feeding, land use, linear programming, location, region selection.

In the past fifteen years, many agricultural economists including Bhagia, Dietrich, Goodwin, and King have set about the task of modeling the optimal location of the cattle feeding industry. Each model has some unique considerations and some considerations that are common to all. The purpose of this paper is to evaluate these considerations to see which ones are most important in determining the optimal location of the cattle feeding industry. In addition, two new considerations are proposed and evaluated.

First, we attempt to evaluate the effect of selection of cattle feeding regions and resource regions on the optimal location of the industry. Different sets of regions are defined for each spatial variable. In addition, the number of regions for each spatial variable is much greater than the number of cattle feeding regions. Second, we postulate that feedlot locations may be affected by regional differences in land use patterns. For example, in the densely populated Northeast, expansion of the feedlot industry would be less likely to occur than in the sparsely populated Southwest.

A linear programming model that minimizes the regional nonfeed costs and the transportation costs of resources and finished product is used. In addition to the new model considerations defined above, the model includes the traditional considerations of feeder cattle, grain and roughage availability, grain and roughage demanded by other animals, and slaughter capacity. Data were developed for the year 1972 from standard U.S. Department of Agriculture publications (1972, 1973a, b). The specific values used in the model, as well as the sources and method of calculation, are shown in Byrkett (1974).

Donald L. Byrkett is an assistant professor of industrial engineering and systems analysis at the West Virginia College of Graduate Studies; Richard A. Miller is an assistant professor of industrial and systems engineering and E. Paul Taiganides is a professor of agricultural engineering at the Ohio State University.

Region Selection

The United States was divided into sixteen cattle feeding regions as illustrated in figure 1. These regions were formed by grouping states around areas of high fed beef production, but individual states were not subdivided in order to facilitate the accumulation of regional data.

Previous studies used the same regions defined for cattle feeding to describe the distribution of each spatial variable. This has two possible disadvantages. First, the regions may not conform to a logical spatial distribution of the given resource. Second, there may be insufficient regions for accurate results. For this study, different regions are defined for each resource. These regions are much larger in number than the number of cattle feeding regions and are designed to describe a logical distribution of each resource. However, as in defining cattle feeding regions, individual states are not subdivided. There are thirty feeder cattle regions, twenty-nine grain regions, thirty-two roughage regions, thirty

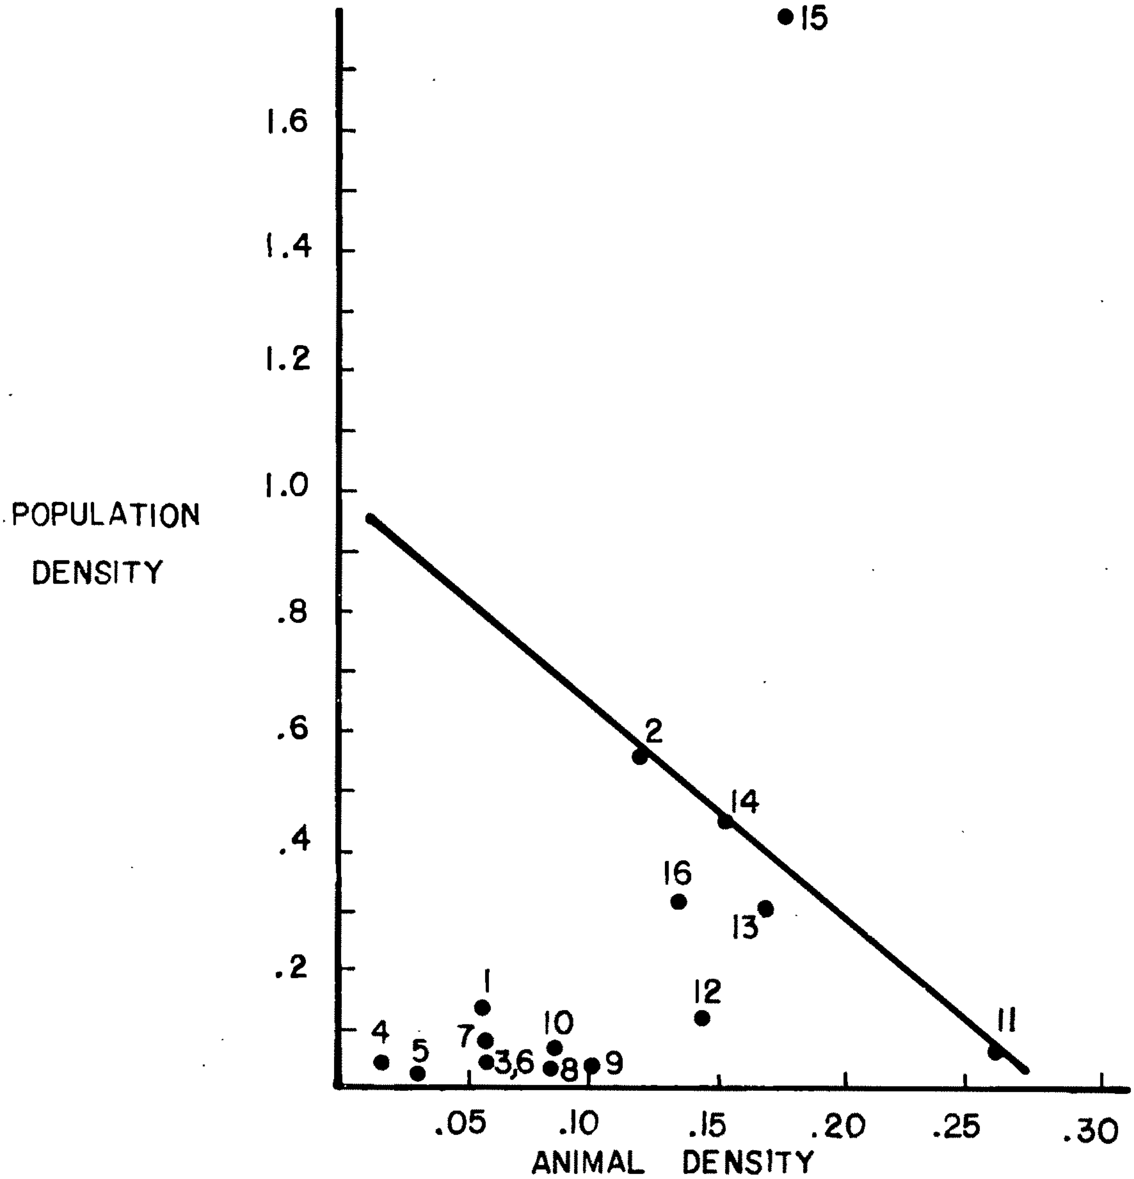

Figure 1. Sixteen cattle feeding regions

slaughter regions, and thirty-two beef demand regions. The assignment of states to regions is contained in table 1.

Regional Land Use Patterns

A new consideration is proposed to limit the expansion of the cattle feeding industry in regions of high competition among alternate uses of the land. This consideration is important for two reasons. First, if the cost of land is extremely high due to the competition for alternate uses, it may be uneconomical to use the land for beef production. Second, in areas of high population density, the conflict between animals and people may limit production. This conflict may arise over such things as odor, noise, or the disposal of wastes.

To model the effect of regional land use patterns on the location of the cattle feeding industry, the regional nonfeed costs per head are permitted to vary according to the production level in a given region. In regions where the competition among alternative uses of land is extremely high, this cost curve rises very rapidly at production levels above the current production level and almost imposes

a constraint. In regions where this competition is low, the cost curve rises very slowly, imposing almost no constraint.

The development of these nonlinear nonfeed cost curves is based on the assumption that areas of high population and animal density tend to have greater competition for land resources and greater conflict between animals and people. Thus, the nonfeed cost curves would rise very rapidly at production levels above the current production. Conversely, nonfeed costs for regions with low population and animal densities would increase less rapidly. This conflict between human and animal population suggests a point at which the two may no longer coexist without nonfeed costs becoming prohibitively high. The approach used to model these increasing nonfeed cost curves was to estimate the increase in production possible in each

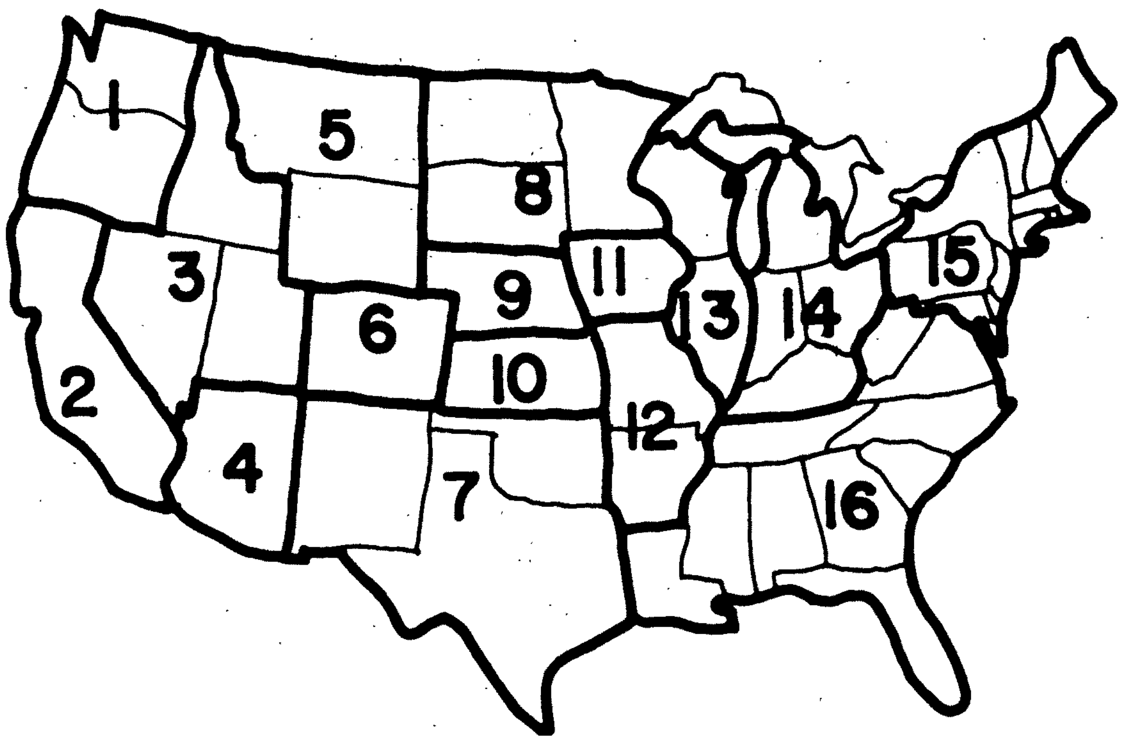

Figure 2. Scatter plot of population density (people/acre of farmland) versus animal density (grain and roughage consuming animal units/acre of farmland) for each cattle feeding region

region before nonfeed costs would become prohibitive. These estimates were obtained by plotting animal density per acre of farmland (USDA 1972, 1973a) versus population density per acre of farmland (USDC 1973, USDA 1973a) for each region as illustrated in figure 2. The line drawn through regions 2, 11, and 14 represents the assumed maximum combinations of human and animal population density possible for the production of feedlot cattle. In these three regions, as well as region 15, cattle production has been declining in recent years (USDA 1973b), concurrent with increasing population/urbanization. Thus, it is assumed that these regions are at or near the maximum level of cattle production possible. Furthermore, it is assumed that region 15 is beyond an acceptable level and that cattle production in this region will continue to decline.[1]

Using this figure, the increase in animal density possible at the current population density was calculated for each region. For example, region 1 has a population density of 0.15 people per farm acre and an animal density of 0.06 grain and roughage consuming animal units per farm acre. At the population density of 0.15, the animal density could increase to 0.24 before hitting the maximum production line. Thus, it is estimated that the maximum production level possible for region 1 is four times the current production level. Similar estimates were made for all regions as follows: region 1—4.0, region 2—1.0, region 3—4.5, region 4—13.4, region 5—9.3, region 6—4.5, region 7—4.4, region 8—3.4, region 9—2.8, region 10—3.4, region 11—1.0, region 12—1.8, region 13—1.1, region 14—1.0, region 15—1.0, and region 16—1.5. Admittedly, little confidence can be placed in the estimated maximum production level but, as indicated in the footnote, we feel that the relative differences between regions are reasonable.

Using this estimate of maximum production level, the following equation was used to represent the inverse relationship between nonfeed costs and production capacity remaining in a given region: $NFC = (MP-CP)\ C/(MP-PL)$, $PL > CP$, where NFC = nonfeed cost (dependent variable), PL = production level (independent variable), C = estimated nonfeed cost at current production level in

[1] To test the sensitivity of this limit, an alternate population limit was evaluated. This case permitted 50% more production before the maximum was obtained but produced little change in the results (Byrkett 1974). It was thus concluded that the important consideration was the relative difference between regions, rather than the absolute increase in production possible.

Table 2. Comparison of Optimal and Actual Production Levels, 1972 (in thousands of head)

Cattle Feeding Region	1972 Actual Production Level	1972 Optimal Production Level	Percentage Deviation from Actual

14	1,256	1,256	0
15	194	194	0
16	628	319	−49

given region, CP = current production level in given region, and MP = maximum production level in given region. The nonlinear nonfeed cost curve resulting from this equation was then approximated by a series of six steps. Each step requires an additional constraint; that is, at step 1, one can produce up to a certain production level at a given cost per head and, at step 2, one can produce up to a higher production level at an increased cost per head and so on.

Base Case

Table 2 contains a comparison of the actual production levels in 1972 and the optimal production levels calculated by the model. By comparing these production levels, one may postulate the areas of growth and decline. Regions 11 through 15 show no deviation from the optimal because it is advantageous to produce as much beef as possible in these regions, but they are limited by the land use constraint to their current production level. In spite of some of the large deviations from actual, the results seem fairly reasonable, since most of these large deviations occur in regions of very small production. The most disturbing result is the large deviation in the optimal production of region 2 (California) from the actual. Recent years have shown a decline in California feeding but not to this extent. However, a sensitivity analysis of the California nonfeed cost lends further support to this decline. The results do support the general conclusions of Dietrich and Goodwin concerning the growth of cattle feeding in the central and southern plains.

Sensitivity of Costs in Base Case

The particular question addressed in this section is the sensitivity of the base case to the estimates of regional nonfeed costs and transportation costs. The approach used was to vary each cost parameter up or down until the solution changed. This procedure was followed for all variables in the basis and the average percentage increase and decrease was calculated for each type of cost. These averages and the upper and lower figure in each average are listed in table 3. This table demonstrates the robustness of the linear programming model, particularly with respect to the

Table 3. Average Percentage Deviation of Basis Variable Cost Parameters without Changing Solution

	Upper Limit			Lower Limit

7	5,939	6,867	5,137
8	1,414	1,781	788
9	4,590	4,890	4,282
10	3,305	3,605	2,804
11	3,986	3,986	3,937
12	638	688	44
13	1,217	1,217	591
14	1,256	1,256	706
15	194	194	194
16	319	628	87

transportation costs. The results indicate that some of the transportation cost figures could be in error by as much as 50% without changing the solution.

On the other hand, the nonfeed cost ranges indicate that even a fairly small error in the estimation of these costs may alter the optimal solution. One could expect that these alterations would have a very direct effect on the optimal location of the cattle feeding industry. With this problem in mind, a further sensitivity analysis was performed on the nonfeed cost parameters. Each nonfeed cost was varied individually by plus or minus 10% to observe the effect on the optimal location of the cattle feeding industry. Table 4 contains the resulting production levels caused by the change in nonfeed cost for each region. This may be compared with the results of the base case to obtain an idea of the range of the resulting optimal solution. The results indicate that a change in nonfeed costs for regions 1, 6, 7, 9, 10, 11, and 15 have little effect on the equilibrium production levels. For region 2, the production should not go below the optimal but may be higher if the nonfeed costs were overestimated. However, this does not change the general conclusion of reduced cattle feeding in California. Regions 3, 4, 5, and 16, although involving large percentage changes, involve very small changes in absolute numbers. For regions 8, 12, 13, and 14, the production should not go above the optimal but may be lower if the nonfeed costs were underestimated.

The main conclusion from this analysis is that nonfeed costs are the most sensitive costs in determining feedlot location, but the possible errors in nonfeed cost estimation are not sufficient to alter the general conclusions obtained.

Analysis of Model Structure

Recall that the objective of this paper is to determine which considerations or factors have a significant impact on the location of the cattle feeding industry. The method of studying these questions is to compare the results obtained without the given consideration in the model to the results in the base case. The assumption is that the base case contains the most accurate results, since it includes all of the considerations. Table 5 contains the results obtained by individually removing feeder cattle constraints, grain constraints, roughage constraints, slaughter capacity constraints, and regional land use pattern constraints, respectively, from the model. In addition, table 5 contains the results obtained by using the same sixteen cattle feeding regions for all spatial variables. The conclusion obtained by removing each type of consideration is discussed in the paragraphs that follow.

Feeder Cattle Availability

The importance of the availability of feeders to regions 2 (California), 3 (Idaho, Utah and Nevada), and 16 (Southeast) is dramatically illustrated as the optimal production in these regions is reduced greatly when feeder cattle availability is no longer considered in the model. Basically, the remainder of the United States is hardly affected except regions 4 (Arizona) and 7 (Southern Plains) pick up the production lost by the other regions.

Grain Availability

Like feeder cattle, it is very clear that grain is an important factor affecting feedlot location as evidenced by the significantly large deviations from the base case. The shortage of grain in regions 2 (California), 4 (Arizona), and 16 (Southeast) is clearly illustrated by the large increases in production that would be optimal

Table 5. Optimal Production Levels without Considering Certain Constraints in the Model (in thousands of head)

		Constraints Not in the Model					
Cattle Feeding Region	Base Case	Feeder Cattle	Grain	Roughage	Slaughter Capacity	Additional Resource Regions	Land Use Patterns

10	3,305	3,305	2,705	3,305	3,305	3,005	5,813
11	3,986	3,986	3,986	3,986	3,986	3,986	4,722
12	638	611	638	638	638	688	0
13	1,217	1,217	1,217	1,217	1,217	1,267	591
14	1,256	1,207	1,256	1,256	1,256	1,256	945
15	194	194	194	194	194	194	908
16	319	87	510	445	678	678	87

were it not for the grain constraints. Conversely, the central area of the United States, regions 7, 8, 9, and 10, would lose some production, if it were not for their advantageous grain position. Though these results are not reported in this paper, it was found that it is not necessary to simultaneously optimize the shipments of grain to cattle feeding regions and grain deficient regions (Byrkett 1974).

Roughage Availability

These deviations are all well within the sensitivity limits of the data established in table 4, and, thus, one must conclude that it was not necessary to model roughage as a factor affecting the optimal location of cattle feeding. This supports the conclusions of Dietrich and Goodwin, who did not include roughage considerations in their models.

Slaughter Availability

The almost negligible effect of slaughter capacity on these results is quite surprising. The only significant deviations are in regions 5 (Montana and Wyoming) and 16 (Southeast). This result is somewhat surprising because this factor has received more discussion in the literature than any of the other factors (Goodwin and Langemeier). This discussion is based on the mobility of slaughter facilities. The other factors are fairly well fixed in their location due to climate and soil conditions, but slaughter facilities may be placed anywhere. This removes slaughter availability from consideration as a fixed constraint.

Spatial Detail

To determine if this extra detail in defining resource regions is really necessary, a model was devised using the same sixteen cattle feeding regions for all of the resources and using the same centers of cattle feeding as the central point for all regions. All of the resource availabilities and beef demand were aggregated to the sixteen cattle feeding regions. All other data remained exactly the same except transportation costs, which were based on mileages between cattle feeding centers.

Table 5 contains the optimal location of cattle feeding as determined from the sixteen region model, that is, without the additional resource regions. These results indicate large differences in five out of sixteen cattle feeding regions, regions 2, 4, 6, 13, and 16. The most significant difference is in region 2 (California), where the optimal production level changed from 872,000 head to 1.601 million head. These results quite vividly indicate the importance of greater spatial detail in defining the resource regions. Using the same sixteen cattle feeding regions for all resources did not provide great enough detail to obtain the accuracy desired.

Regional Land Use Patterns

This factor has a tremendous impact on the regional location of cattle feeding as illustrated by the significant differences in regions 7, 8, 10, 11, 12, and 15. One might also add that the results obtained using this factor agree much more closely with 1972 data, which increases confidence in the validity of the model. For example, the optimal production in region 15, without considering the regional land use patterns, is nearly five times the current production. Clearly, it is unrealistic to expect this kind of growth in the Northeast. Naturally, when the Northeast is limited to the more realistic current production, other eastern regions, regions 8, 12, 13, 14, and 16, are brought up to more realistic levels.

Summary and Implications

A cost-minimization linear programming model was developed to model the optimal location of the cattle feeding. The following results were obtained. (*a*) Feeder availability and grain availability strongly influence the location of cattle feeding. (*b*) Roughage availability is not a primary concern in the location of cattle feedlots. (*c*) Slaughter capacity will influence the location of cattle feeding in the short run, but in the long run slaughter facilities will move to the feedlots. (*d*) In modeling the location of cattle feeding, it is important to use a greater number of resource regions than cattle feeding regions. (*e*) Land use patterns that reflect both the competition for land resources and the conflict resulting from efforts to eliminate problems associated with odors, solid waste disposal, and water pollution in areas of high population density is an important factor influencing the location of cattle feeding.

These results have strong implications in several areas affecting the cattle feeding industry. Recent trends (Nicol and Heady) show that the proportion of feeder cattle production is increasing in the Central Plains and the Southeast and that the proportion of grain production is increasing in the Lake States, Corn Belt, Southern Plains, and the Southeast. Due to the importance of these factors of production, one may expect cattle production to continue to decline in coastal areas and to increase inland.

The effect of increasing fuel or transportation costs is somewhat uncertain. (Byrkett 1974). Fuel costs for transporting feeders and grain may be minimized by feedlot location in the inland states, while fuel costs for transporting the beef to market may be minimized by feedlot locations near the coastal population centers. These opposing forces in conjunction with the insensitive nature of the transportation costs tend to counterbalance each other in determining feedlot location.

Changes in cattle feeding technology may effect the location of cattle feeding in three ways. First, as commercial feedlots become more dominant, nonfeed costs will become more competitive in some regions. For example, Corn Belt nonfeed costs are much higher than those in the Southern Plains due partly to the greater proportion of farmer feeders. Thus, increasing commercialization will lower certain nonfeed costs and, due to the sensitive nature of these nonfeed costs, trends in cattle feeding production may change.

Second, changes in cattle feeding technology may allow cattle and people to live in harmony and thus reduce the important land use conflict consideration. For example, the feedlot of the future may be a multistory building that is completely enclosed and odor free with a total waste recycling and/or composting operation. This type of facility may be no more obnoxious than a typical midwestern manufacturing plant and thus fits in better with the structure of society in the population centers.

Third, new environmental requirements may effect nonfeed costs differently throughout the country. Byrkett (1975) found that the Federal Water Pollution Control Act Ammendments of 1972 will have little effect on the location of cattle feeding but given the sensitivity of these nonfeed costs, later changes in the legislation may alter this conclusion. Incidentally, these results are in agreement with those published by Forster indicating the small effect of this legislation on Michigan cattle feedlot performance.

Framework for Economic Analysis of Grain versus Harvested Roughage for Feedlot Cattle

Ray F. Brokken, T. M. Hammonds, D. A. Dinius, and John Valpey

Traditional models for assessing technical and economic efficiency of cattle feeding were found inadequate. An alternative framework is developed for estimating effects of changes in ration nutrient concentration on animal performance under a range of production conditions and types of animals. The framework is incorporated in a dynamic profit function and its use discussed and demonstrated under various optimizing criteria. High energy rations remained economical even at relatively high grain prices. This framework implies sigmoid shaped grain-roughage isoquants; concave to the origin over the finishing range of grain-roughage ratios, and convex at lower grain-roughage ratios.

Key words: beef, cattle, efficiency, feed energy, feedlot, optimum rations, rations.

Cattle are versatile animals and can be grown on diets varying widely in the proportions of grain and roughage. Over most of the past several decades, the cost of growth in cattle has been lower in the feedlot than on pasture or range, and the cost per calorie of net energy has been lower from grains than from roughages. Now, because of generally higher feed prices and changes in the price of grains relative to roughages, questions are raised about traditional rations and even whether cattle should be grown in feedlots at all. Answers to these questions involve physical and economic efficiency considerations, consumer preferences, and ethical and political considerations as well. Certainly, political and ethical considerations should be based on knowledge of physical and economic efficiencies and the trade-offs involved and not on misinformation about them.

The authors have observed much misunderstanding about the basic relationships and trade-offs by those concerned with these issues, including not just the popular press and lay public, but agricultural economists and animal scientists as well. Such misunderstanding can lead to perverse recommendations and policy. Contributing to this misunderstanding is the fact that traditional analytical frameworks are inadequate.

The primary purposes of this paper are to present a technical framework for estimating the voluntary feed consumption and performance of different types of cattle for diets ranging widely in nutrient and energy concentration, to describe the technical information needed to bring the framework to its full potential in economic analysis, and to illustrate use of the technical framework in economic analysis.

First, some traditional analytical approaches and their limitations are discussed. Second, the general framework for describing voluntary feed intake and research needed to bring it into a more complete operational level is presented. Then, voluntary intake and energy requirements functions are specified for three animals that allow estimation of total feed requirements and growth from diets ranging widely in roughage and grain content. Finally, a dynamic profit function and an economic analysis of grain-roughage substitution is presented. The primary focus of the

paper is on the technical research needs and its primary contribution is as a guide to some further multidisciplinary animal research.

The results of the economic analysis are interesting, because they suggest that a high concentrate diet remains economical even at quite high grain prices. However, the main contribution of the economic analysis is in illustrating the workings of the technical framework and theory in the economic model and in illustrating the potential economic importance of further technical research.

Traditional Approaches

The production function with isoquants, expansion lines, and ridge lines provides a traditional model for economists. A casual mental construction of technical substitution between roughage and grain in the finishing phase of beef production may suggest an optimum balance that is very sensitive to small shifts in ratios of ingredient prices. However, this has not been the case.

Feedlot rations in recent years have typically contained only what is regarded as a physiological minimum of roughage. Not only has grain been much cheaper per unit of net energy but less net energy is required to produce a given gain from the higher concentrate rations. The reason for the latter point is that higher roughage rations require more days of animal maintenance to produce a given amount of growth than do high concentrate rations. Hence, the optimum combination of grain and roughage has been firmly located at the ridge line defining a physiological (or a safe) minimum level of roughage.

The grain to roughage price ratios of a few years ago were such that a very large increase in the ratios was necessary to move economically away from the minimum roughage ridge line. Movement along the isoquant away from this point entails more time, yardage, feed preparation, and interest, items that are easily overlooked in casual analysis with this framework.

It is very difficult to explicitly incorporate rate of gain, time, difference between animals, specific beginning and ending weights, and other complicating variables into the traditional production function framework. For this reason, the framework has never proved practical in commercial application and has only limited usefulness in theoretical considerations.

The California net energy system (Lofgreen and Garrett, National Academy of Sciences) has provided a very useful estimate of energy requirements for maintenance and growth for many, but not all, animals. This system also provides an improved basis for assessing relative feed values of various ingredients for use in ration formulations with linear programming (Brokken 1971a, c; Scott and Broadbent). A major difficulty in applying this system over diets ranging widely in energy content is the lack of information about how voluntary feed (energy) intake is affected by changing the energy concentration (calories per pound) of the diet.

Montgomery and Baumgardt (1965a) have proposed a general relationship to describe feed intake regulation in relation to dietary energy concentration. At low levels of ration energy concentration (calories per pound of ration), intake is limited by stomach capacity, but as a certain level of energy concentration is reached, the rumen fill ceases to limit intake and further increases in ration energy concentration result in a decrease in feed intake (see figure 1). While dry matter (DM) intake is declining at the higher energy intake, the higher energy concentration permits approximate maintenance of digestible energy intake. This has led to the conclusion that with diets such that rumen fill is not limiting intake the animal consumes for its needs in terms of its inherent genetic capability for growth. How-

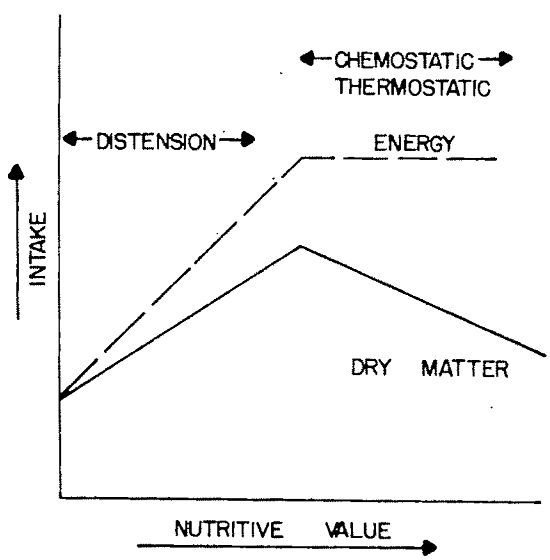

Figure 1. Proposed relations in regulation of feed intake in ruminants (Montgomery and Baumgardt)

ever, it is known that net energy (NE) as a proportion of digestible energy (DE) increases as the DE concentration increases. Then, if DE intake were to remain constant as ration energy concentration increases, NE intake must be increasing. This implies an increasing rate of gain as ration energy concentration increases, which is indeed the case. Further, if daily dry matter intake, Y, is a linear function of energy concentration, X; i.e., if $Y = f(X)$, then energy intake, $XY = X\,f(X)$, is nonlinear and vice versa. Figure 1 is inconsistent in this respect. However, the empirical work of Montgomery and Baumgardt (1965a), Dinius and Baumgardt, and Dinius et al. corroborates the dry matter intake relationship. These relationships have been reexamined and are reported in detail elsewhere (Brokken and Dinius 1974, 1976; Dinius et al.). Their work provides a framework which accommodates differences between individual animals for estimating the effect on voluntary daily feed intake and daily gain of changing dietary energy concentration. In figure 1 voluntary daily dry matter intake is increasing to a peak then decreasing as energy concentration increases. To the right of the peak it is hypothesized that chemostatic and/or thermostatic mechanisms regulate intake. To the left of the peak, gut fill limits intake. However, the daily intake declines leftward with decreasing energy concentration because the rate at which the feed is digested slows and daily additions to the rumen are therefore decreased. These facts must not be ignored in fitting production functions. Data should be separated into two sets when the experiment involves diets that occur in the two different phases of intake regulation. If data are combined and an overall function is fitted, significant distortions in the isoquants and other relationships could result. A diagram of isoquants implied by our proposed framework is presented later.

General Technical Framework

Let the appetite of the ith animal, as it relates to calories per kilogram (energy concentration) of its diet, be described as

$$(1) \qquad Y_i = A_i/X + B_i,$$

where Y_i is the kilograms of daily voluntary dry matter intake (DMI) divided by its metabolic size ($W_i^{0.75}$), W_i is the body weight of the ith animal, and X is the calories per kilogram of the diet measured in terms of net energy for gain (NE_g).

Then, the daily intake of energy is DMI multiplied by dietary energy concentration:

$$(2) \qquad XY_i = A_i + B_iX.$$

Alternative algebraic forms (e.g., $Y = A'_i + B'_iX$ and $XY_i = A'_iX + B'_iX^2$) and implications for gain have also been tested (Brokken and Dinius 1974, 1976). There were no meaningful differences in the fit or in implications between the two sets of relationships.

By expressing net energy for maintenance (NE_m) concentration as a function of NE_g concentration in the California net energy system (National Academy of Sciences), their daily net energy requirements functions may be rewritten as

$$(3) \quad XY_i = 0.08089X - 0.03185X^2 + bg_i + cg_i^2,$$

where g_i is gain in kilograms per day (for steers, $b = 0.05272$ and $c = 0.00684$; for heifers, $b = 0.05603$ and $c = 0.01265$). Dividing equation (3) through by X, we obtain DMI requirements per unit metabolic weight in terms of dietary energy concentration and gain.

Equating equations (2) and (3) and solving for g_i,

$$(4) \quad g_i = -\frac{b}{2c} + \left[\left(\frac{b}{2c}\right)^2 + \frac{(A_i + B_iX + 0.03185X^2 - 0.08089X)}{c}\right]^{\frac{1}{2}}.$$

This system is diagrammed in figure 2. In chart C of figure 2 the curves for two animals are parallel. This implies that voluntary energy intake curves, chart D of figure 2, are divergent, which implies that performance of the animal with the higher potential for voluntary intake is affected by changes in dietary energy concentration more than animals of lower growth potential. The reader can follow through the implications of functions that converge in chart C in a manner to allow parallel curves in chart D.

How can the coefficients A_i and B_i be defined? What is the difference in voluntary DMI at a particular energy concentration between any of the ith animals ($i = 1, 2, \ldots, n$) and some arbitrary animal, say $i = 0$? Obtaining $Y_i - Y_0$ from equations (1) and (3), solve for $A_i/X + B_i$:

$$(5)\quad A_i/X + B_i = A_0/X + B_0 + \frac{b}{X}[g_i(X) - g_0(X)] + \frac{c}{X}[(g_i(X))^2 - (g_0(X))^2],$$

where $g_i(X)$, $i = 0, 1, 2, \ldots, n$, is a value for gain per day that is consistent with each value of X as in equation (4).[1]

A_0 and B_0 are estimated by directly observing Y_i for $A_i/X + B_i$, the rate of gain of each animal at each energy concentration for $g_i(X)$, and the mean gain of animals at each energy concentration for $g_0(X)$. To specify A_i and B_i, two additional hypotheses are required. Hypothesis I is the case of parallel appetite functions with corresponding divergent energy intake functions, i.e., $A_i = A_0$, $i = 0, 1, 2, \ldots, n$, and $B_i \neq B_0$. Hypothesis II is the case of converging appetite functions with corresponding parallel energy intake functions, i.e., $B_i = B_0$ and $A_i \neq A_0$. Obviously, other possibilities exist, but these two are convenient starting points and have quite different implications for the optimum dietary energy concentration for animals of different growth rates. These two hypotheses are illustrated graphically in figure 2 and for our numerical example in figure 3. It should be understood that while the foregoing arguments are couched in terms of differences between two individual animals, the important point of interest has to do with differences between animals of high gain potential as a group and animals of lower gain potential.

[1] The case where rate of gain declines throughout the feeding period was not encountered and remains to be worked out. Simulations of errors under conditions of other than a constant rate of gain showed only minor errors from the assumptions of constant (mean) gain over the entire period under most typical gain trajectories; usually from 0.1% to 1.0%. For the case of a substantial and long term decline or increase in gain per day, the assumption of constant gain may introduce substantial bias depending on the length of feeding period. In this case, we propose the following modification of equation (5): $Y_{ikt} = A_0 + B_0 X_k + \frac{b}{X_k}(g_{ikt} - g_{0k}) + \frac{C}{X_k}(g_{kit}^2 - g_{0k}^2)$, where k represents the kth level of energy concentration and t represents the tth feeding period.

B. DAILY VOLUNTARY ENERGY INTAKE

Figure 3. **Daily voluntary dry matter and energy intake for three animals**

Needed Development

The case of calves versus yearlings is an interesting one in the context of different gain potential. Yearlings generally gain faster than calves in the feedlot. If appetite functions for yearlings and calves tend to be parallel (and voluntary energy intake functions divergent), then reductions of ration energy concentration will reduce energy intake and rate of gain in the yearlings more than in calves and their optimum diets may differ.

For the case of heifers versus steers, or the case exotics versus English breeds, the body energy parameters, b and c, of equation (3) must also be differentiated (the curves in charts A and B of figure 1 would be steeper for steers than for heifers and steeper for the English breeds than for the exotics). The heifers are likely to gain less per day than steers, but the energy per unit of their gain at any given body weight is greater. Therefore, heifers may consume as much or more dry matter per unit metabolic size per day but gain less weight than steers. The coefficients of net energy requirements for gain are differentiated for steers and heifers by the National Research Council (NRC) (National Academy of Sciences), but further differentiation is needed for bulls of the English breeds and for heifers, steers, and bulls of the large (exotic) breeds. The general appetite model equation (5) should also be separated by differentiating the energy parameters b_j and c_j for the jth class of animals. Corresponding adjustments throughout the system would follow.

In addition to differences in growth potential, several other factors affect parameters of the appetite functions. For example, it is known that stress reduces the appetite. Further, ration heat increment (HI) relative to NE_g is higher in roughages than in grain. Hence, we would expect the appetite function (figure 2, chart C) to be lower and flatter under heat stress than under a thermal neutral condition. Since practically no two ingredients have the same ratio of metabolizable energy (ME) to NE_g, two different blends with the same overall concentration of NE_g will have different ME concentration, therefore different heat increments. In fact, the relative HI of diet can be varied widely for any but the maximum level of NE_g concentration (Brokken 1971b; Lofgreen). In light of the newer interest in high roughage rations, more work is needed to establish optimum rations for hot and cold weather. Physical form of the ration (pelleted, flaked, high moisture, ground, etc.) also affects intake and the steepness of the appetite function (McCroskey et al., Cullison). Pelleting high roughage rations increased DMI but decreased it in high concentrate rations.

A great deal of work remains to be done on the subject of grain-roughage substitutions in cattle feeding. We believe this analytic framework offers improved coherence to the manifold factors involved and can serve as a basis for designing many additional feeding trials.

Perhaps a meaningful approach would be to develop a somewhat arbitrary standard set of relations for one type of animal under carefully controlled and described environmental conditions with carefully developed diets having a given set of nutrient-energy ratios, etc. Then as important deviations from the environmental conditions, physical form of the diet, etc., were studied, a set of operating rules could be developed to appropriately modify the standard functions so that the system applied better to conditions of a particular application. If sets of functions for different types of animals grown under the same conditions were significantly different, standard sets of functions with appropriate operating rules could be developed for different types of animals.

Three Animals

We now specify appetite and energy requirements functions for three animals. The reason for using three animals is to illustrate better the economic importance of some possible variations in the appetite functions and in the functions for daily energy requirements for maintenance and gain. The first animal represents the sample mean of animals in an experiment designed to estimate an appetite function and test the hypotheses of converging and parallel appetite functions. In this experiment (Dinius et al., Brokken and Dinius 1976), each of five diets varying in digestible energy (DE) from 3.605 to 2.804 million calories per kilogram were fed to four Angus and four Santa Gertrudis yearling steers. Corresponding NE_g values, derived from NRC formulas (National Academy of Sciences), varied from 1.28 to 0.778 million calories per kilogram. Protein-energy ratios were constant for all diets, and the environment was virtually free of climatic stress. Roughage used in the experiments was high quality hay, half alfalfa and

half orchardgrass. All rations were ground and fed as a complete mix. Other work corroborates these general findings but stops short of a framework for deriving parameters as a function of growth capability and for analyzing efficiency implications (Montgomery and Baumgardt 1965a, b; Dinius and Baumgardt).

It was established that though cattle will eat more pounds of the higher roughage rations per day, net energy intake is less than from rations of higher grain content. Appetite functions for faster and slower gaining animals were exactly parallel (hypothesis I) but statistically did not preclude convergence (hypothesis II). Actual mean feed (energy) intake levels and mean rates of gain are closely approximated by the derived functions of each of the five energy levels used in the experiment.

The hyperbolic appetite function that was derived from the experiment (Brokken and Dinius 1974, 1976) is used for animal 1:

$$(6) \qquad Y_1 = 0.0625/X + 0.04279.$$

Daily net energy requirement per unit of metabolic weight of the experimental sample is

$$(7) \qquad XY_1 = 0.05222 + 0.05412g_1,$$

where g_1 is the rate of gain for animal 1. Combining equations (6) and (7),

$$(8) \qquad g_1 = (XY_1 - 0.05222)/0.05412 = 0.18995 + 0.79065X.$$

While equation (7) predicted the energy requirements for the experimental sample of animals quite well, it was derived from a rather small sample (forty animals, twenty Angus and twenty Santa Gertrudis) and deviates significantly from NRC functions for maintenance and gain (National Academy of Sciences). On the other hand, the NRC functions have predicted animals' feed requirements and performance on high energy diets quite well in many commercial operations. These animals had to have appetite functions that passed through a point that was consistent with the feed (energy) intake described by the NRC function (equation (3)). Suppose the appetite functions for animals 2 and 3 are, respectively, convergent and parallel with the appetite function of animal 1. Suppose further when $X = 1.28$, both will gain three pounds per day (1.36 kilograms), then

$$(9) \qquad Y_2 = 0.08153/X + 0.04279 \text{ (converges to } Y_1\text{)},$$

$$(10) \qquad XY_2 = 0.08153 + 0.04279X \text{ (parallel with } XY_1\text{)},$$

$$(11) \qquad Y_3 = 0.0625/X + 0.05766 \text{ (parallel to } Y_1\text{)},$$

and

$$(12) \qquad XY_3 = 0.0625 + 0.05766X \text{ (diverges from } XY_1\text{)}.$$

To obtain $g_2(X)$ and $g_3(X)$ equate equations (10) and (12), respectively, to equation (3) and solve for g_2 and g_3 as in equation (4). The three appetite functions and corresponding voluntary daily energy intake functions are shown in figure 3.[2]

Total feed requirements over a span of time or weight gain can be calculated in several ways. The following method has proven useful with very low aggregation error under most gain trajectories. Feed intake on day t is

$$(13) \qquad YW_t^{0.75} = Y(W_0 + gt)^{0.75},$$

where W_0 represents the weight, when $t = 0$.

Total feed (TF) over n days is

$$(14) \qquad TF = Y\int_0^n (W_0 + gt)^{0.75}dt = \frac{Y}{1.75g}[(W_0 - ng)^{1.75} - W_0^{1.75}].^3$$

Weight on the nth and final day of the feeding period is $W_n = W_0 + ng$. Hence, total feed over the span of weight from W_0 to W_n is

$$(15) \qquad TF = \frac{Y}{1.75g}[W_n^{1.75} - W_0^{1.75}].$$

Both Y and g are functions of X; or, for a given X, Y can be expressed as a function of g.

Profit Function

Profit, π, is total revenue (TR) minus total cost (TC):

$$(16) \qquad TR = 0.96PW_n,$$

where P is market price and 0.96 is $1 - s$, where s is the shrinkage factor. Also,

---

[2] The observation points for figure 3 are adjusted within each diet by $Y_i - 0.05412\,(g_i - \bar{g}_k)/X$ and $XY_i - 0.05412\,(g_i - \bar{g})$ for charts A and B, respectively. Without these within diet adjustments for differences in dry matter (energy) intake owing to within diet differences in gain, some of the observation points would lie well above the curves Y_2 and Y_3 in chart A and above XY_2 and XY_3 in chart B. Hence, all three examples developed here lie well within the intake observations of the experiment.

[3] In the case where feed intake per unit metabolic weight and gain per day decline continuously at a substantial rate, the integral should be broken up into a series of two or more segments of time or in the extreme, discrete summation day by day should be used.

(17) $$TC = (1 + rn)P_0W_p + \left(C_x + \frac{rnC_x}{2} + C_p\right)\frac{Y}{1.75g}(W_n^{1.75} - W_0^{1.75}) + nC_n + (1 + rn)K_1 + K_2,$$

where r is daily interest rate; n is $(W_n - W_0)/g$, the number of days in the feedlot; P_0 is purchase price; W_p is the payweight; Y is feed per day per unit metabolic weight; g is weight gain per day; C_x is the minimum feed cost per kilogram of feed for a given energy concentration with appropriate concentrations of other nutrients; C_p is feed preparation cost per kilogram of feed; C_n is yardage cost per day; K_1 is acquisition costs including commissions, trucking, vaccination, dipping, etc., and K_2 is fixed cost on equipment and facilities.

Under most custom feeding contracts, K_2 is treated as a variable cost and is included in feed preparation ("feed mark up") and yardage, i.e., in C_p and/or C_n. Such contracts discriminate slightly against adjustments to rations with lower energy concentration from the cattle owner's standpoint.

As a practical matter, it is difficult to define marginal revenue with respect to body weight or with respect to days on feed when price takes discrete jumps as slaughter grade changes or if market price is changing for any reason. Once the animal has reached the grade of Good, the marginal revenue from the grade of Good to Choice (MR_{G-C}) is

(18) $$MR_{G-C} = (P_C - P_G)0.96W_G + 0.96P_C(W_C - W_G),$$

where P_C and P_G are, respectively, the expected slaughter prices for Good and Choice, and W_G and W_C are, respectively, the expected slaughter weights for Good and Choice.[4] The returns from price spread between Good and Choice are often greater than the returns from weight added between the two grades. Hence, even though marginal cost exceeds the expected Choice slaughter price, it is often economic to continue feeding to Choice as both more weight and a higher price per pound are produced.

For most of the past thirty years it has been very economical to feed to Choice grade. The major exceptions have been in cases where $P_C < P_G$, owing to a negative time trend in the market or to the case where the animal will not achieve Choice grade for genetic reasons. While at any point in time $P_C > P_G$ for those animals that will achieve higher grades, several additional days of feeding are required to go through the Good grade to reach Choice.

In situations as in late 1974 when marginal cost exceeds expected slaughter price throughout most of the potential feeding period, the only source of profit is in developing a positive price spread between the slaughter price and the purchase price. When price spreads are positive, the optimum weight may exceed to point where marginal cost is equated with expected slaughter price. In this case, the optimum weight balances the losses from the weight added against the gains from price spread. This weight could occur at any point between where marginal cost equals expected market price and a point where further increases in weight are discounted in price. Marginal cost (MC) with respect to weight is[5]

(19)
$$MC = \partial(TC)/\partial W_n = \frac{rP_0W_p}{g} + (C_x + C_p)\frac{Y}{g}(W_n^{0.75}) + \frac{rC_xY}{3.5g^2}(2.75W_n^{1.75} - 1.75W_0W_n^{0.75} - W_0^{1.75}) + C_n/g + rK_1/g.$$

Marginal cost with respect to time is g times marginal cost with respect to body weight:

(20) $$\partial(TC)/\partial n = (\partial(TC)/\partial W_n)g.$$

Let W^* be the weight at which MC equals expected slaughter price discounted for shrinkage, i.e., where MC = $0.96P$:[6]

(21) $$W^* = \left[\frac{0.96P_g - rP_0W_p - C_n - rK_1}{(C_x + C_p)Y}\right]^{\frac{1}{0.75}}.$$

The value of n at the point where $0.96Pg = \frac{\partial(TC)}{\partial n}$, n^*, is

(22) $$n^* = (W^* - W_0)/g.$$

Because expected slaughter price is not marginal revenue, W^* cannot be construed as an

[4] Average market price (AP) of a pen of animals may be a continuous function of average pen weight: $AP = \Sigma\alpha_iP_i$, where P_i is market price of the ith grade and α_i, the proportion of animals in each grade, is a function of the average pen weight.

[5] Set $n = W_n/g - W_0/g$ in equation (17) to calculate MC.

[6] In calculation of W^*, the term for marginal interest on feed, the third term in the right hand side of equation (19) was dropped. This term complicates calculation of W^* enormously but has only a minor effect on its value.

optimum market weight. To develop an expression for the optimum market weight, we must express P in the numerator of equation (21) as a function of weight. The reader can sympathize with the difficulty of deriving such an expression or in solving it once it was derived short of an iterative approximation method. The present analysis is sufficiently served by numerically evaluating the profit function at different slaughter grades.

Elsewhere in this issue Wilson approaches the analysis of forage-grain trade-offs from the criterion of daily returns above feed costs. In our notation, his criterion is

$$\pi' = Pg - C_x Y W^{0.75}. \tag{23}$$

His analysis is quite legitimate from the point of view of selecting diets that will maximize profit per head per unit time and provides a different and complimentary perspective to the approach in this paper. However, negative daily returns in equation (23) will occur at approximately W^* or n^*, respectively, from equations (21) or (22). Since this criterion cannot deal with returns from price spreads, its use is limited to analysis of optimum diets under the criterion of maximizing returns per head per unit time.

Profit per Unit Time

Since costs are based on daily inputs, the costs and return per unit time are easily obtained. Average profit per day is π/n. Under full feedlot utilization, the criterion becomes profit per animal per day. The maximization of π/n without consideration of time preference occurs when (Dillon, p. 73)

$$\frac{\partial(TR)}{\partial n} - \frac{\partial(TC)}{\partial n} = \frac{TR - TC}{n}. \tag{24}$$

In contrast, profit per animal is maximized when marginal revenue equals marginal cost, i.e., when

$$\frac{\partial(TR)}{\partial n} - \frac{\partial(TC)}{\partial n} = 0. \tag{25}$$

Since a major part of the returns may be obtained from increasing price per pound by increasing quality grade, the weight at which a given animal is slaughtered may not vary between optimizing criteria. The greater difference might be in the time required to obtain that weight, though in many instances the different criteria would obtain the same diet also.

As long as feedlot capacity is under utilized, the focus of analysis tends to be on profit maximization per animal. However, even in the case of less than full utilization of feedlot capacity, there may remain the issue of profit per unit time for calves versus yearlings. Since yearlings are typically fed only about half as long as calves, the same profit per head would give a yearling feeding program about twice as much profit per head per unit time as a calf feeding program. A similar point applies to optimum market weights, e.g., the same profit per head for Good and Choice grades would imply greater profit per unit time at the lower grade. The same profit per head for two different diets implies greater profit per unit time for the shorter feeding period.

The degree to which profit per unit time is an issue and alters production from maximization of profit per head will vary from firm to firm and as market conditions vary from year to year and through the cattle cycle. It should be remembered that annual profits to the firm are to be maximized, and this is not necessarily consistent with maximization of profit per animal per unit time even in the case where the firm has no other enterprise. In any case, when profits are positive, the use of more roughage in the finishing stage fares better relative to high concentrate diets under the criterion of maximizing profit per head than under maximizing profit per head per unit time. The following analysis emphasizes the case of profits per head, but profit per head per unit time is also calculated.

Analysis

The profit function derived in the previous section is evaluated numerically for all three animals. Five different diets and two different market weights are used. The diets vary in NE_g concentration from 0.9 to 1.3 million calories per kilogram; the market weights (including a 4% arbitrary shrink) are 456 kilograms (1,005 pounds) grading Good and 475.2 kilograms (1,048 pounds) grading Choice.

Two sets of ration ingredient prices are used with one set of feeder calf and slaughter prices and one set of feed preparation, yardage, and fixed costs. The ingredient prices are those that prevailed in Eastern Nebraska in November 1974 and March 1975. Slaughter

Table 1. Ration Cost and Expected Average Gain for Three Animals by Ration Energy Concentration

Item	Ration Energy Concentration (MCal NE_g/kg) 0.9	1.0	1.1	1.2	1.3
Ration Cost[a] (¢/lb., 100% dry basis [% roughage])					
Nov. 1974	4.03 (53)	4.52 (42)	5.08 (33)	5.64 (23)	6.20 (16)
Mar. 1975	3.40 (53)	3.74 (42)	4.16 (32)	4.58 (23)	5.00 (14)
Average Gain (lb./day)					
Animal 1	1.99	2.16	2.34	2.51	2.69
Animal 2	2.64	2.71	2.80	2.91	3.04
Animal 3	2.46	2.58	2.72	2.88	3.05

[a] Eastern Nebraska quotations for Nov. 1974 and March 1975, respectively: corn, \$3.40 and \$2.75/bu., corn silage (at 6 bu. corn plus \$3/ton, 28% dry basis), \$23.40 and \$19.44/ton; alfalfa, \$55.50 and \$49.00/ton; mixed hay, \$46.00 and \$45.00/ton; soybean meal, \$10.50 and \$7.26/cwt; urea, \$10/cwt for both periods; salt and minerals, \$5.40/cwt for both periods.

prices are for Good and Choice animals in Nebraska in March 1975 with feeder calf prices of November 1974.

The first section of table 1 shows the total ingredient cost per pound and the approximate proportion of roughages for each ration, for both sets of ingredient prices. The second section shows the average rate of gain from beginning to end of the feeding period, g_i (different from payweight to payweight rate of gain, g'_i), for each of the three animals on each ration.

Feed preparation costs are C_p = \$3 per ton; yardage, C_n = \$0.04 per day; acquisition and start-up costs, K_1 = \$8.55; fixed costs, K_2 = \$14.80; annual rate of interest, 8%; purchase weight, W_p = 315 kilograms (694 pounds); purchase price, P_0 = \$30.80 per hundredweight; and market price is \$35.20 per hundredweight for Good and \$36.40 per hundredweight for Choice.

Profit and other variables calculated from equations (16) and (17) are shown in tables 2, 3, and 4, respectively, for the three animals under the five diets. Calculations using the March 1975 and November 1974 feed prices

are summarized, respectively, in the middle and lower parts of each table.

Using March 1975 feed prices, the high energy ration is most profitable (least unprofitable) for all three animals, and the Choice grade is the most profitable market weight for all rations given that feeding is going to take place. Of course, no losses would be encountered if feeding was not initiated in the first place. Because the beginning and ending shrinkage in weight can be spread over more time in going on from Good to Choice, the payweight to payweight gain per day (g'_t) increases as the number of days on feed and grade increases. Break-even purchase prices (BEPP) appear to be well below cost of producing yearling feeders. The March 1975 slaughter prices were quite low and have since risen well above the break-even market price (BEP), which would cover all costs at zero

[a] See footnote of table 2.

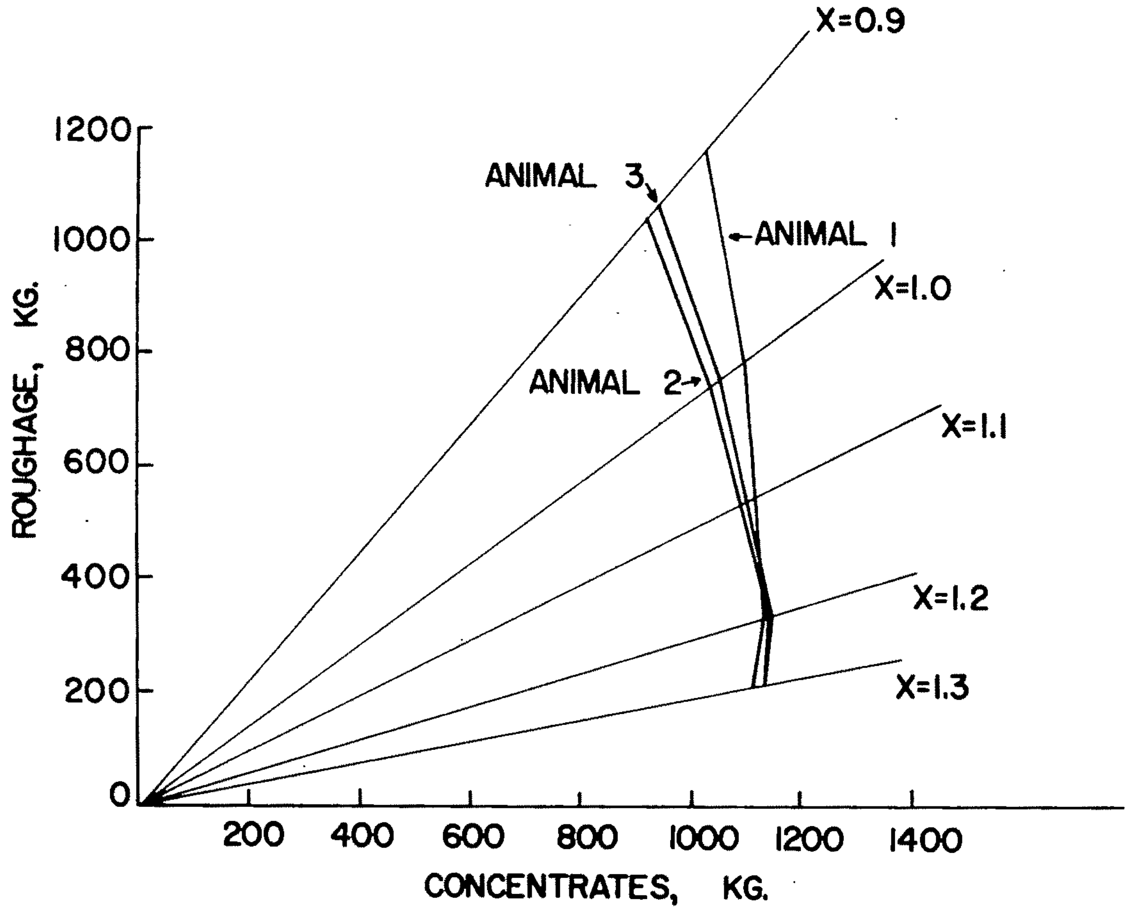

Figure 4. Isoquants derived from the appetite functions and feed requirements functions using diets of table 1 for animals 1, 2, and 3

profit given the purchase price of the animal and other costs. Average cost of gain, (COG), i.e., total cost of gain divided by total payweight to payweight gain, decreases as the fixed costs are spread over more weight added. The argument that feeding animals to heavy weights is wasteful is not supported by average COG calculations.

Corn prices were substantially higher in November 1974 than in March 1975. For November 1974 feed prices, the highest concentrate diet was still the most profitable for animal 1 (table 2). The Choice slaughter grade is the more profitable grade for all three steers in every case except for animal 1 with the high roughage diet where Choice and Good are equally profitable (rounded to the nearest dollar). However, the cost of gain and break-even prices show a small advantage for Choice grade in this case also. The price margin between Good and Choice used was only $1.20 per hundredweight. The optimum market weight remains unchanged over diets, even though the MC function increased as dietary energy concentration decreases. The issue in optimizing weight becomes feeding for price margin, i.e., feeding to obtain a higher price per pound by increasing quality grade. Further, the best diet for feeding to Choice grade is also the best one for feeding to any lower grade once the animal enters the feedlot. When cost of gain exceeds expected price per pound and price margins are positive, the strategy is not to sell at lighter weights but to buy heavier feeder cattle, thereby securing the revenue from price margin with a smaller expenditure of feed and time.

The low concentrate diet is the most profitable for animal 2, while for animal 3 profits were equal for the high concentrate and low concentrate diets. The fact that the optimum diet appears to swing from high concentrate to the low concentrate diet suggests a linear or concave isoquant for the roughage-

concentrate substitution relationship. Total profit divided by number of days on feed, π/n, is negative in every case. Maximizing profit per head per unit time seems a dubious criterion when it is negative. While the high roughage diet will give a lower average loss per day in some cases, one is committed to more days and a larger eventual loss per head. The criterion seems to make more sense in the case of positive profits.

Implied Isoquants

Isoquants strike a familiar chord with economists and can help to place many of the technical issues into clearer perspective. The authors believe that the technical aspects of the problem must be well understood by economists in order for them to serve well in further multidisciplinary research on this subject.

The implied roughage-grain isoquants can be plotted by connecting the coordinates for total roughage and total concentrates required in the production of an animal of a given final weight for each of the five diets. Total roughage (TROU) is

$$(26) \qquad TROU = q(TF),$$

and total concentrate (TCON) is

$$(27) \qquad TCON = (1 - k - q)TF,$$

where TF is taken from equation (14), q is the proportion of the ration that is roughage (table 1), and k is the proportion of nonenergy bearing ingredients such as salt, minerals, vitamin mix, urea, etc. These coordinates are plotted on figure 4 for each of the three animals. Notice that the isoquants are concave to the origin!

The data plotted represent only the upper range of ration energy concentration, i.e., the range where gut fill (distention) does not limit intake (see figures 1 and 3). For the implied roughage-grain isoquant to become convex to the origin, the appetite function must become much steeper than those found in this study or become steeper by taking the form of a function that is decreasing at an increasing rate. However, for the present sample, the hyperbolic function that decreases at a decreasing rate fits the data slightly better than the linear function.

In the low range of energy concentration where gut fill (distention) limits intake (see figure 1), our calculations showed that isoquants are convex to the origin for all likely appetite functions in this range, i.e., for all functions between a horizontal line and a 45° line through the origin that intersect with Y_1 (equation (6)) at $X = 0.78$. This evidence suggests we may expect S-shaped isoquants for many cattle feeding situations.[7] The shape of the isoquant is also affected by the many factors influencing the appetite function, which were cited earlier as needing further research.

The implications of concave isoquants for feeding trial experiments and feedlot management are important. For example, feeding trial experiments might focus only on the very high concentrate diets and on diets that approach the point where gut fill becomes the constraining mechanism on daily feed (energy) intake. Diets in between these two extremes are likely to be uneconomical relative to either extreme. This issue needs immediate further exploration from both hypothetical simulations and empirical experimentation.

Summary and Conclusions

It is suggested that much of the present confusion regarding the economics of cattle feeding and optimum rations is due to the inadequacy of traditional analytical frameworks for dealing with these complex issues. A technical system that relates cattle performance to ration nutrient concentration is developed by combining daily voluntary feed (energy) intake as function of ration energy concentration and animal weight (an appetite function) with daily feed (energy) requirements for maintenance and growth as a function of rate of gain and animal weight. The system appears very promising for assessing the efficiency of animal production under a wide range of diets and production circumstances for different types of cattle. The experiment and the analytical framework on which the economic analysis rests need to be expanded to cover more situations known to affect the voluntary feed and energy intake.

A dynamic profit function that incorporates the daily performance functions is developed and an economic analysis for three different animals is made. Results of this analysis show

[7] John T. Scott, Jr., called our attention to slightly concave isoquants indicated in the work of Goodrich et al. This article is based on data from seventeen midwestern university experiments, in which rations of varying proportions of corn silage and corn were tested.

that high energy rations remain optimum under rather high grain prices in many cases.

In an important sense, the conclusions based on this model are conservative. The ratios of roughage to grain prices used are lower than what exist in many regions. Including fixed costs in variable costs as "feed mark-up" or "yardage," a common practice in custom-feeding contracts, discriminates against high roughage diets. Fixed costs were separated from variable costs in this analysis. Price spread between Good and Choice was very small. The appetite function for animal 2 favors roughage most, but is the least consistent with the experimental results. Finally, profit per head was considered rather than profit per unit time.

The most surprising result is that the roughage-grain isoquant implied from the system is concave to the origin over the high energy range of feedlot diets and convex to origin on low energy diets. This result seems plausible in light of the probable shapes of the appetite functions and feed transformation function. Failure to recognize the potential for S-shaped or sigmoid isoquants may have distorted the results of some previous work.

Our main conclusions are that this important issue is complex and remains unresolved, that establishing a coherent set of experiments and data for general analysis of this problem remains a challenge, and that the analytical framework presented here is useful in addressing this challenge.

National Food Policy for an Interdependent and Uncertain World (Luther Tweeten, Oklahoma State University, Chairman)

Do We Need a National Food Policy?

H. S. Houthakker

The title of this paper was changed from the one that the organizers gave me not merely because of a dislike of prolixity but also for more substantive reasons. The original title was "Do Consumers or the Nation Need a National Food Policy?" It reflected the division of labor between Seevers and myself, with his speaking about food policy from the producer's point of view. I recognize, of course, that there is a producer's point of view, and I have no doubt he will give it adequate weight. Nevertheless, I feel that if we, that is, the consumers, do not need a national food policy, then it is not likely that producers are justified in asking for one.

To say that national policies have to be oriented towards consumers rather than producers may betray a total lack of political sensitivity. We all know that policies for particular industries, be it energy, transportation, or steel, are generally initiated and supported by producer interests. However, this paper deals with policy rather than politics, and approaches the subject from an economist's point of view. That point of view, by and large, is a consumer's point of view.

By way of further introduction, let me say something about the notion of a national policy without regard to its subject. Consider the industry that economists have studied most thoroughly, the widget industry. If someone calls for a National Widget Policy, we can be sure that he wants the government to do something. Doing nothing is not generally considered a policy, even though it may be the best approach the government can take. Furthermore, to be worthy of the name, a National Widget Policy would have to have some degree of internal consistency; a panoply of contradictory measures presumably could not be described as a national policy.

It follows that the desirability of a National Widget Policy should be judged against two alternatives, one being government abstention) the laws and regulations remained in sures. It is the latter alternative that people usually have in mind when they call for a national policy. The very nature of the political process makes it inevitable that government intervention in any industry is beset by contradictions. Many government measures were originally motivated by immediate problems, but even after these problems had disappeared (whether or not as a result of government action) the laws and regulations remained in force. An important reason for this persistence of obsolete programs is that each of them has usually acquired a constituency of its own. A major effort is therefore needed to get rid of government programs that have outlived their usefulness. Nevertheless, it can be done, as the abolition of the sugar program in 1974 shows.

In the area of food policy, there are also many contradictions. Although the price support programs for basic crops are no longer effective, certain other agricultural programs continue to raise food prices. This is especially true of federal and state marketing orders and of import restrictions on dairy products and meat. Offsetting these producer-oriented programs, there are others, such as food stamps and the school milk and school lunch programs, that tend to lower prices. These contradictions bring us back to the other alternative to a national food policy, namely, abstention from government intervention.

The papers in the "Proceedings" section were presented at the winter meeting of the AAEA held in conjunction with the Allied Social Science Associations in Dallas, December 28–30, 1975.

H. S. Houthakker is a professor of economics at Harvard University.

The author is indebted to Data Resources, Inc., for access to its system and to Edward Schuh for useful references.

The Justification of Government Intervention

Whether the government can abstain from intervening in food matters depends primarily on the effects of unfettered operation of the market mechanism and more particularly on the effects on consumers. The question is whether the free market can produce adequate food supplies at reasonable prices. It need hardly be said that the terms "adequate" and "reasonable" are imprecise, but that is no reason for ignoring the question. The interpretation of these terms is essentially a matter of political judgment. In present circumstances food supplies will only be considered adequate if all, or virtually all, consumers are able to maintain a diet that meets certain nutritional standards.

In other words, there should be no involuntary malnourishment among domestic consumers. Two adjectives in this sentence need emphasis: "involuntary" and "domestic." The first refers to the well established fact that even in some high income households diets are insufficient by these nutritional standards because of "dieting" or ignorance; this is clearly not an economic problem but rather (if it is a problem at all) an educational one. As regards the restriction to domestic consumers, while there are certainly people who are concerned about the adequacy of nutrition in other countries, it can hardly be said that there is a national consensus to this effect. In fact, the maintenance of nutritional minima on a global scale would be a staggering task and would raise serious questions of population policy.

At first sight, government intervention in individuals' food purchases may appear to be in conflict with consumers' sovereignty, a notion dear to economists' hearts. Why not let households buy as much or as little food as they want at prices reflecting the social cost of production? If households cannot buy enough food because of poverty, the answer would be income supplements rather than subsidies linked to specific expenditures.

These are weighty, and generally valid, considerations. Nevertheless, there are good grounds for not relying entirely on the response of households to market forces. In particular there is reason to fear that in families with low food consumption the children are at a special disadvantage, not merely in their current intake but, more importantly, in that their physical and intellectual development may be stunted. To the extent that these children are in schools, they can be reached by such programs as school lunches and school milk. The problem of preschool children, however, is inherently more difficult; indeed, it is the most compelling, not to say the only valid, justification for government intervention. The situation here is similar to that in education, where parents also cannot always be counted upon to make socially optimal investments in the human capital of their children.

The principal drawback of government programs to improve nutrition by food subsidies is that they may be made available to many people who could perfectly well take care of their own nutrition. This danger is all the more real because food programs, while ostensibly directed at consumers, often derive some of their political support from producers anxious to expand their markets. Despite this danger, the microeconomic justification of these programs is not open to serious question.

Another argument for government intervention in the food markets is based on the relative volatility of food prices, which are strongly affected by the weather and by variations in demand (especially from abroad). There is little doubt that this volatility makes life difficult for producers, who are often unable to protect themselves (by hedging or forward contracts) against sudden falls in output prices or rises in input prices. Greater price stability can therefore promote efficiency in food production, which also benefits consumers provided there is active competition. It is not equally clear that price stability provides any other advantages to consumers. Nevertheless, rises in food prices—especially in highly visible meat prices—are very unpopular, although price falls are barely noticed. From a political point of view, stabilization of food prices therefore is generally desirable.

The Demand for Food in the United States

Although there is justification for some degree of government intervention in food consumption, the extent of this intervention should depend on the general performance of the food markets. To correct particular problems, such as occasional malnutrition or excessive price instability, is one thing, but to view these markets as unable to function without official

direction is quite another thing. Market performance is determined in part by the responsiveness of supply and demand to price changes. In a well functioning market, prices have to adjust frequently in order to even out fluctuations in supply and demand caused by exogenous determinants, whereas in a malfunctioning market prices tend to be rigid while supply and/or demand fluctuate sharply.

A detailed evaluation of the performance of the food markets, which would require an examination of the supply side, is beyond the scope of this paper. Let us just recall that numerous studies have found the price elasticity of food supply to be significantly positive, at least after sufficient time for adjustment. (See, for instance, Tweeten and Quance.)

On the demand side the evidence is not as clearcut, especially where food as a whole is concerned. In Houthakker and Taylor, for instance, a number of demand equations for food are reported, but prices were not significant in several of them. These equations were based on aggregate time series for the period 1929–64 (or sometimes 1947–64), and one reason for the insignificance of prices may have been that until the 1970s the relative price of food as a whole did not vary much because of price support programs. A variable with a small variance is not likely to be picked up by regression analysis.

With the gradual termination of these programs, food prices became more volatile, a development reinforced by the gradual disappearance of surplus stocks. For most of the 1950s and 1960s the Commodity Credit Corporation held large inventories, but they were reduced by such events as the failure of the Indian monsoon in 1966, the corn blight of 1970, and finally the Russian grain deal of 1972. In the last few years inventories in the United States (and hence, for most practical purposes, in the world) have been uncomfortably small, a matter further discussed below.

It is an ill wind that blows nobody any good, and the inflation of 1972–74 together with the recession of 1974–75 produced a great deal of potential information concerning the effects of price and income changes. Moreover, there are now quarterly national accounts data on consumers' expenditures on food and beverages at current and constant prices for the period 1953–75.[1] These show a rise of more than 12% in the relative price of food starting in late 1971 and continuing through early 1974. Per capita food consumption, which of course is also affected by income, fluctuated irregularly during the first half of the 1970s, with a marked decline in 1973 when the relative price was rising most steeply.

Various linear and double-logarithmic equations have been fitted to quarterly data from 1953 through the second quarter of 1975. There is not much to choose between these equations; the following appears to be the most useful.

$$
\begin{aligned}
(1)\quad \ln q_t = {} & -\underset{(-6.4)}{0.554} + \underset{(5.4)}{0.457}\ln q_{t-1} \\
& + \underset{(6.5)}{0.181}\ln y_t - \underset{(4.5)}{0.139}\ln p_t, \\
& \bar{R}^2 = 0.982;\ DW = 1.72,
\end{aligned}
$$

where ln is the natural logarithm, q_t is per capita food consumption at 1958 prices in period t, y_t is per capita personal disposable income, deflated, and p_t is the relative price of foods as defined in note 1. The t-ratios are given in brackets; they are satisfactorily large. This equation implies an income elasticity of 0.18 in the short run and of 0.33 in the long run. The price elasticity is -0.14 in the short run and -0.26 in the long run.[2] Although fairly small, the price effects are quite significant from a statistical point of view and also important for the subject of this paper, since the performance of a free market depends in part on the responsiveness of the demand side to price changes.

The Demand for Food Abroad

Since the United States is a major food exporter, the price of food in this country is heavily influenced by foreign demand. It is therefore of interest to estimate the price elasticity of food demand abroad. A comprehensive analysis would meet with serious data problems, but valuable insights can be obtained by looking at a few countries for which comparable data are available for a sizable number of

[1] From now on, the term "food" will tacitly include beverages. The absolute price of food was calculated by dividing the constant-dollar expenditure into the corresponding current-dollar figure; the same was done for consumers' expenditure on all items. The relative price of food is the ratio of these two implicit deflators.

[2] These long-run elasticities are considerably smaller in absolute value than those estimated from annual data in Houthakker and Taylor. Although the model used there was linear rather than double-logarithmic, this does not appear to account for the discrepancy, which may be related to a defect in the dynamic specification of the underlying model of consumer behavior.

years.[3] The time series for these countries were pooled, that is, the same regression coefficients were assumed to apply to all countries; the intercepts, however, were allowed to differ so as to absorb currency and other statistical differences. The counterpart of equation (1) for the seven countries is

$$(2) \quad \ln q_{it} = a_i + \underset{(12.1)}{0.756} \ln q_{it-1} + \underset{(3.9)}{0.155} \ln y_{it} - \underset{(-1.4)}{0.130} \ln p_{it}, \qquad \bar{R}^2 = 0.986,$$

where the variables are the same as in equation (1), except for the additional subscript i indicating the country. The intercepts a_i are not relevant for the present purpose and have therefore not been calculated; the squared correlation coefficient from pooled time series does not have a straightforward interpretation and is given only for completeness.

In comparing equations (1) and (2), it should be borne in mind that equation (2) is based on annual data. The short-run elasticities with respect to income and price (here, 0.16 and −0.13, respectively), while apparently similar to those in equation (1), do not mean the same; in fact, to be consistent with equation (1) the short-run elasticities in equation (2) would have to be three or four times as large. The long-run elasticities, which are 0.63 for income and −0.53 for price in equation (2), are conceptually comparable with those in equation (1), but much larger. Actually what matters here is not so much whether the elasticities are different in the United States from those abroad but whether the price elasticities are significant. In this respect, equation (2) leaves much to be desired since the t-ratio for p_{it} is only −1.4. A better equation is

$$(3) \quad \Delta \ln q_{it} = a'_i + \underset{(5.8)}{0.340} \Delta \ln y_{it} - \underset{(5.2)}{0.534} \Delta \ln p_{it}, \qquad \bar{R}^2 = 0.351,$$

where Δ is the first-difference operator and the intercepts a'_i now represent the residual trends prevailing in each country. The lagged dependent variable is absent from equation (3), so an interpretation in terms of short and long run is no longer possible. Although the discussion in Houthakker (1965) suggests that equation (3) reflects primarily short-run effects, the estimated elasticities in equation (3) are actually closer to the long-run elasticities implied by equation (2). This implies once more that the dynamic assumptions underlying these equations need further examination.

Composition of Food Consumption

Notwithstanding these problems, it seems fair to conclude from the econometric analysis that the demand for food is responsive to price changes. It is also important to know whether the pattern of food consumption depends on prices, for it is sometimes maintained that the industrialized countries are inexorably bent on consuming more meat and other livestock products in lieu of crop products. Since grain fed to livestock produces fewer calories for human consumption than grain products consumed directly (for instance, in the form of bread), this allegation would imply that the rich countries, by insisting on meat, are causing starvation in the poor countries. While a full investigation of this question would lead us too far afield, it is interesting to see what has happened in recent years to the balance between livestock products and crop products.

This is done in table 1, which breaks down calories and proteins per head per day into crop products and livestock products for those OECD countries, not all of them highly industrialized, for which data for 1955–59, 1965–69, and 1973 are available.

Inspection of table 1 confirms the almost universal shift towards livestock products, but in many countries consumption of grain products (as measured by calories) also went up. In fact, most countries witnessed an increase in total calorie intake per head; it is especially pronounced in what were (and sometimes still are) the poorer countries: Italy, Japan, Por-

[3] Data were taken from the Organization of Economic Cooperation and Development, *National Accounts of OECD Countries*. (The most recent printed version covers the years 1962–73, but data from 1960 on were used here.) These data cover not only food and beverages but also tobacco. For seven countries (Australia, Belgium, Canada, Finland, Germany, Italy, and Japan), data were available for the entire period 1960–73, and these were the countries used here. The variables used are generally the same as in the U.S. analysis (see note 1), except that personal disposable income had to be calculated from "current receipts of households" by subtracting direct taxes on income and social security contributions; it was deflated by the implicit deflator for total consumption. Midyear population figures were taken from *International Financial Statistics*. Despite standardization by OECD, conceptual differences among the national accounts data of different countries are inevitable but believed to be minor. In two cases, missing observations had to be obtained from national sources.

tugal, Spain, and Yugoslavia. The shift towards livestock products implied an increase in protein consumption in the large majority of countries, though in most of them protein consumption has stayed well below the U.S. level.[4]

[4] According to the spring 1965 Household Food Consumption (USDA 1965–66), the average protein consumption of American

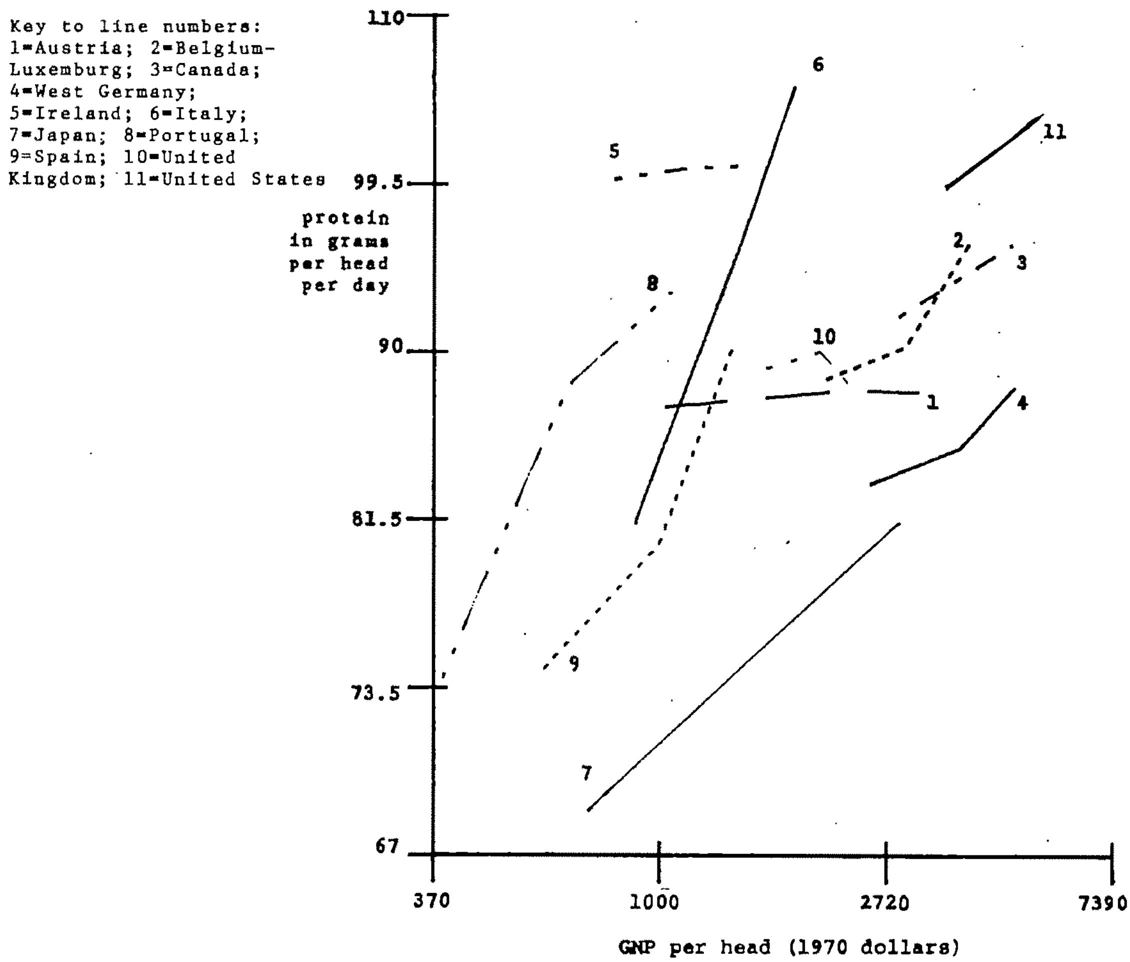

Figure 1. Protein consumption in relation to GNP per head

In figure 1, the data on total protein consumption from table 1 are plotted against per capita GNP in 1970 dollars at 1974 exchange rates.[5] Each of the eleven lines links the three observations for one country, and both variables are on a logarithmic scale. While the dispersion is considerable, some tendency towards a flattening towards the right-hand side of the chart can be detected; generally, the slopes are steeper for the low income countries at the left, except for Ireland, where protein consumption was high throughout the period of observation.

It is too early to say whether the increase in protein consumption is indeed slowing down, and these data also shed little light on the effect of relative price changes on the composition of food consumption. Pending further evidence, the worries about the effects of increasing consumption of livestock products on world nutrition can therefore not be dismissed lightly.

Nutrition in the United States

Let us now turn to the most important concern that a national food policy is intended to deal with, namely, domestic malnutrition. Detailed statistical evidence on this problem is available mostly from the 1965–66 Household Food Consumption Survey, which shows, not surprisingly, that malnutrition is associated with low incomes. However, some malnutrition is also found among higher income households.

households with incomes over $15,000 was 113.7 g.; the average for all households at that time was 105.8 g.

[5] The GNP (or in some cases Gross Domestic Product) was used instead of personal disposable income because otherwise too many countries would have dropped out for lack of consistent data; even so, six of the seventeen countries in table 1 could not be included in the chart. Exchange rates for 1974 were used because the adoption of floating in 1973 probably made them more realistic than in previous years.

Table 2. Percent of Households with Various Dietary Deficiencies

		% of Households with Less than Recommended Allowance		
Income Group	Number of Households in Sample	In One or More Nutrients	In Three or More Nutrients	Two-Thirds Less In One or More Nutrients
Under $3,000	1697	63	22	36
$3,000–4,999	1515	57	17	24
$5,000–6,999	1756	47	14	18
$7,000–9,999	1360	44	10	12
$10,000 and over	790	37	10	9

Source: As in note 4, pp. 5, 6, 14.

The adequacy of nutrition was measured in this survey by converting observed consumption of a large variety of foodstuffs into nutrients by a standard formula and comparing the calculated nutrient consumption with the recommended allowances of seven important nutrients (protein, calcium, iron, vitamin A value, thiamine, riboflavin, and ascorbic acid); there was no physical examination of the households' members. No attempt could be made here to verify the validity of these allowances or of the methods by which they were compared with actual consumption. No doubt these survey data are also subject to sampling fluctuations and to systematic biases inherent in household surveys, especially if they extend only over one week, as was the case here.

Table 2 gives some overall measures of the nutritional adequacy of household diets by income group. The correlation with income is evidently close. Further examination shows that three of the seven nutrients, namely, calcium, vitamin A value, and ascorbic acid (vitamin C) are particularly likely to be below the recommended allowance. For two of those (calcium and ascorbic acid), this is shown graphically in figure 2; the pattern for vitamin A is somewhat intermediate between the two shown. In figure 2, the full bar indicates the percentage of households that fall short of the recommended allowance, while the cross-hatched part gives the percentage of those who do not even reach two-thirds of the allowance.[6]

[6] Another report in the same series (no. 17) relates dietary adequacy to per capita expenditure on food. Although $5 per person per week was theoretically sufficient to meet all recommended allowances at the time of the survey, three-quarters of the households who spent between $5 and $7 per week were deficient in at least one nutrient. Even of households spending between $12 and $16 per week, one-quarter did not meet all recommended allowances. Sampling errors aside, this suggests that many households either do not agree with these nutritional requirements, or that they consider other aspects of food (such as palatability and variety) more important.

Malnutrition and Market Imperfection

Is it a coincidence that the three nutrients in which dietary deficiencies are most common are also the ones for which the market is least perfect? The principal source(s) of calcium is milk and of vitamins A and C are fresh fruits and vegetables, in addition to citrus juices. These are precisely the commodities for which marketing orders have long been used to restrict competition among producers. In the case of dairy products, where important restrictions are an additional barrier to competition, the main effect of marketing orders is to prevent, or at least severely limit, interregional flows of milk from undercutting local milk producers. Dairy cooperatives have organized so-called superpools to strengthen their market power, and their exercise of political pressure can without exaggeration be called scandalous. That their practices place a heavy financial burden on consumers is well known but that artificially high milk prices are also a major cause of malnutrition appear to be less widely realized.[7]

In many fruits and vegetables, marketing orders, reinforced by the antitrust exemption of farm cooperatives, are being used to restrict supply; California oranges and Florida tomatoes are two examples among many. Since production of specialty crops is often confined to one or a few small areas, supply control is not difficult to achieve, provided the government is willing. Destruction of so-called surpluses, whether before or after harvest, is a common practice in certain treecrops. Admittedly, there are special problems in the marketing of perishable fruits and vegetables

[7] The dairy interests sometimes claim in defense that many dairy farmers are poor. If so, one major reason appears to be that low-cost dairy producers are not permitted to sell in their best markets.

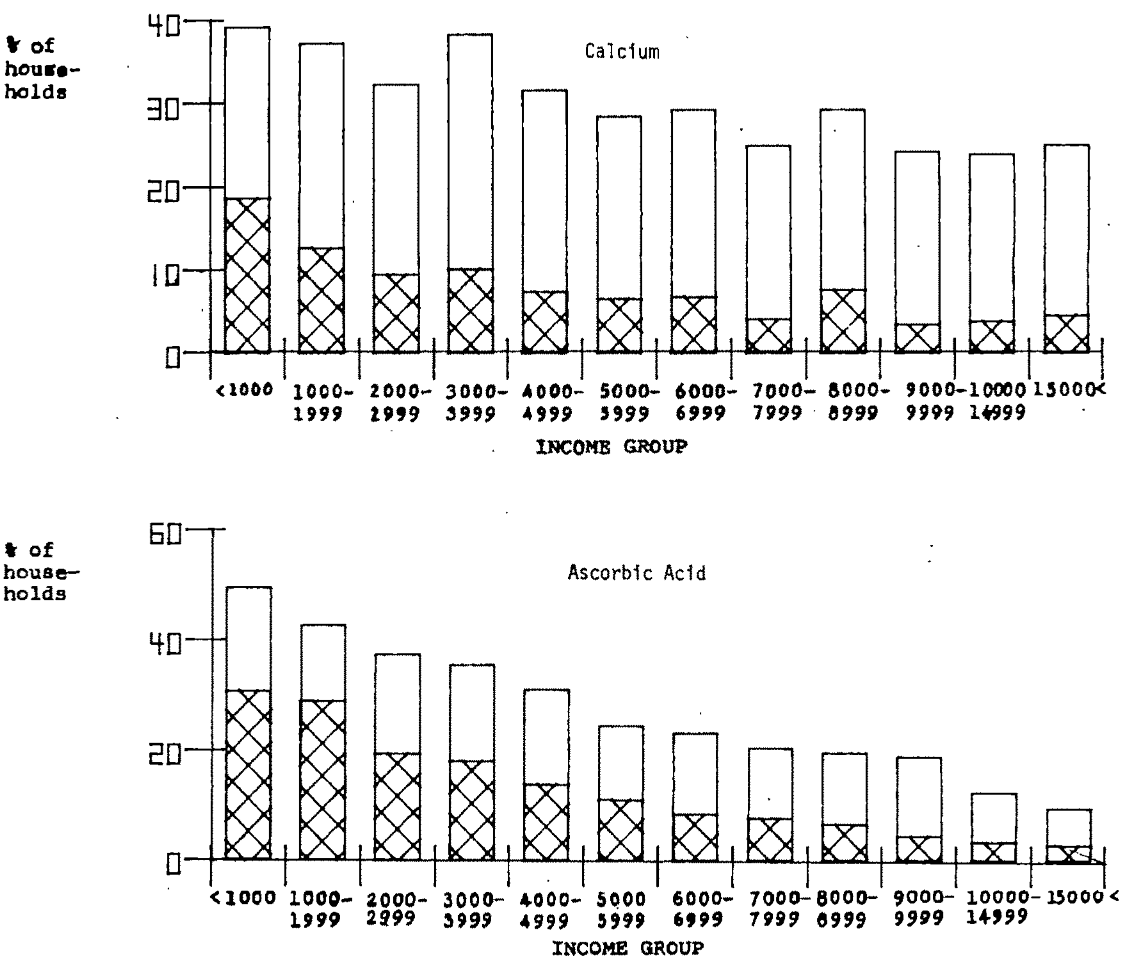

Figure 2. Nutritional inadequacy

when the bulk of the crop becomes available in a short period of time, but that does not justify government intervention at the expense of consumers.

The Food Stamp Program

After this digression from the main subject of this paper, it is time to go back to the consumer. In recent years the main activity of the Federal government on behalf of consumers has become the food stamp program. From a small start in the early 1960s it has been expanded in stages, and at present involves budget expenditures at an annual rate of well over $5 billion; the number of beneficiaries is now approaching twenty million. Originally intended mostly to increase the demand for food, it has now become one of several overlapping programs to counteract poverty.[8] Under this program eligible households are entitled to stamps that can be used like money in the purchase of domestic foodstuffs and certain inputs into food production. Eligibility is determined by income and family size, and these factors also determine how much participating households must pay for the stamps. Thus, in early 1975 a four-person household was entitled to stamps with a face value of $154 per month, for which it would pay nothing if its net money income was below $30 per month, $53 at an income of $200 per month, and $130 at an income of $500 per month. Four-person households with monthly incomes over $513 were not eligible.

The program therefore can in principle have

[8] As Browning has pointed out, the effects of these programs on the distribution of income is hard to analyze from published statistics, which refer only to money income. According to his calculations, the distributive effect has been substantial, although it has been accomplished at a relatively high cost because subsidies linked to particular expenditures (such as food and housing) are inherently inefficient in raising real income.

two effects on participating households: it increases their disposable income by the money value of the bonus stamps (those received free of charge), and it reduces the relative price of food. These two effects offset each other. Since the stamps can be used only to buy food, their money value is less than their face value. It appears, in fact, that food stamps are traded at about half their face value.

While these two effects are fundamental in analyzing the impact of food stamps, the problem is complicated by the fact that some participating households would have spent more on food than the face value of their stamp entitlement (the $154 per month just mentioned for four-person households) even if they had received no stamps at all. Such households presumably use the stamps to pay for their accustomed food bill. Their disposable income rises by the full face value of the bonus stamps, but the relative price of food to these households does not fall. (For a detailed analysis see Clarkson.) Their food consumption would rise only by what they spend on food out of the increase in disposable income. This is not to be considered a defect of the program, whose principal economic justification is that it enables poor families to attain an adequate diet. It represents, however, a rather complicated way of raising the disposable income of households who are probably relatively well off to begin with.

In its present form and coverage the food stamp program is too new to permit conclusive evaluation of its effects on the demand for food.[9] The size of the food stamp program, as measured by budget expenditures (U.S. Dep. of the Treasury), was introduced as an explanatory variable in the demand analysis for the United States discussed earlier in this paper, but it was either not statistically significant or significant with the wrong sign.[10] There are as yet no comprehensive cross-section data, similar to the 1965–66 Household Food Consumption Survey, in which food stamps are isolated as a factor influencing food purchases, but such data are expected to be available in 1976. Aggregate data on nutrition do not suggest any marked change in the nutritional status of the population in recent years (USDA 1975); an increase in the availability of vitamins A and C is offset by a decrease in calcium.

The Role of Inventories

In addition to concern about malnutrition, the second justification for a national food policy admitted in this paper was excessive fluctuation in food prices due to inadequate inventories. As figure 3 shows, there has indeed been a considerable fall in inventories since the middle 1960s. In 1974 stocks of both wheat and corn at the end of the crop year (July 1 for wheat, October 1 for corn) were at record lows, yet at the same time foreign demand for our crops was particularly intense. Increased exports had been a major factor in the rise in food prices during the Great Inflation of 1972–74, and they had also depleted our inventories.

The international aspect of inventory policy, in fact, is of crucial importance. For several basic farm products, including those charted in figure 3, the United States is now the world's supplier of last resort, a position attributable to the efficiency of our farmers and merchants and of such marketing institutions as the Chicago Board of Trade. In addition, our agricultural policies have long favored—indeed, sometimes overstimulated—farm exports, to the benefit of farm income and the balance of payments but occasionally at the expense of domestic consumers. The natural desire of farmers for profitable overseas markets has increasingly clashed with consumers' concern over sudden rises in food prices.

It would take great confidence in the efficacy of the political process to argue that it could resolve this conflict better than the free market.[11] Nevertheless, there may be a case for improving the stability of the free market, that is, for reducing the probability of sharp price fluctuations. Because of the large risks involved, the stocks held by private operators may be smaller than is socially optimal, and prices may be correspondingly more volatile. The Commodity Credit Corporation, what-

[9] A recent government study (Reese, Feaster, and Perkins) is largely inconclusive, although it does find that in 1972 the aggregate demand for red meats was 0.85% larger as a result of bonus stamps. Clarkson reports that food stamps did not account for the relative improvement in per capita disposable farm income (p. 81). He also presents estimates of the benefits to participating households.

[10] The latter finding is presumably due to multicollinearity. The recent massive expansion of the program coincided with a rise in the relative price of food and a fall in real disposable income. Future observations may make it possible to disentangle these effects.

[11] Some government intervention is needed, however, in the case of exports to communist countries whose monopsonistic buying practices have at times (especially in 1972) constituted a disruptive abuse of market power. The recent agreement with the Soviet Union promises to be helpful in this respect.

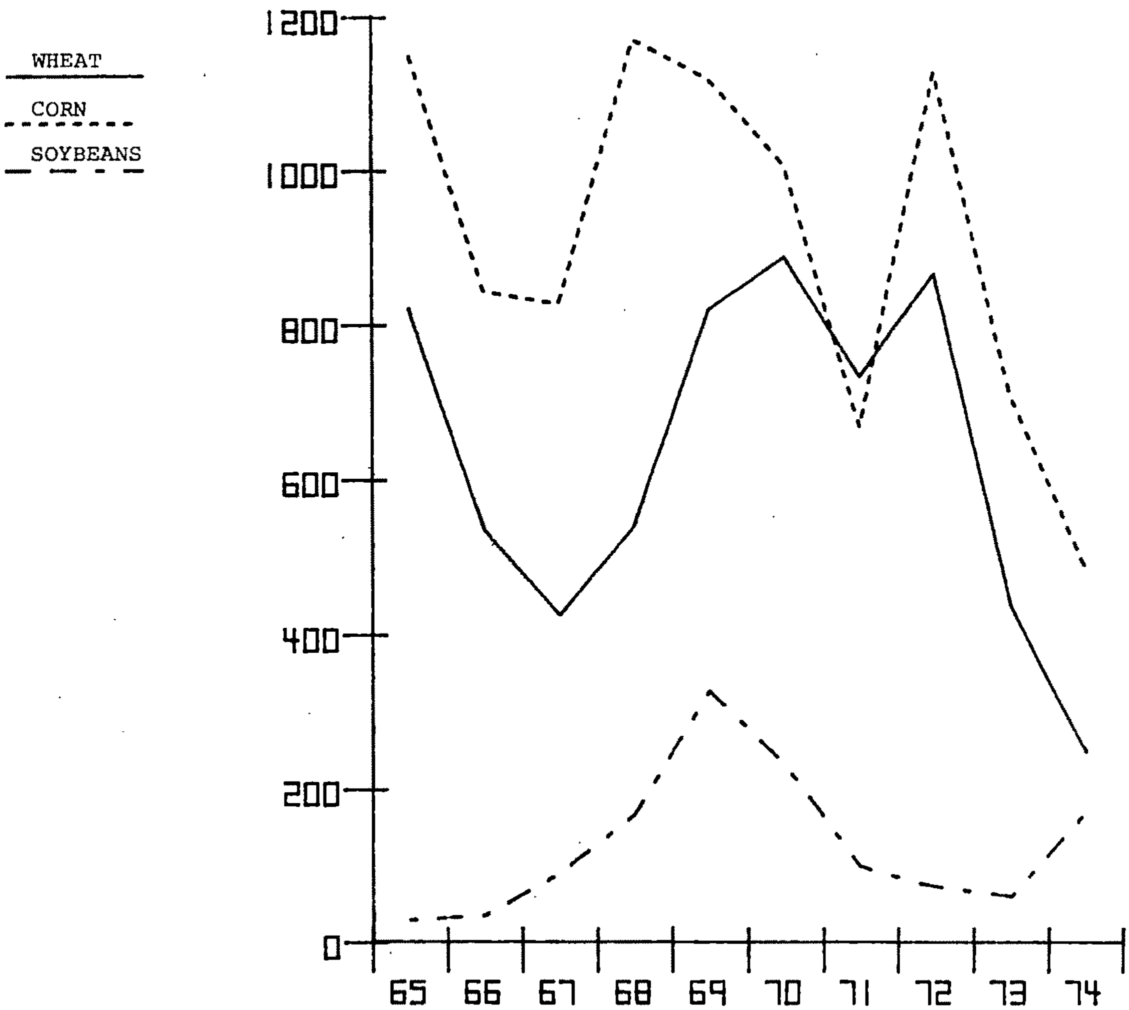

Figure 3. Carryover stocks

ever else it may have done, did help keep prices stable when it carried large inventories, but it no longer does. In any case it is not clear that government stocks are desirable for this purpose, since their acquisition and release may be subject to political pressures. To do the most for price stability, the inventories should probably be partly in the hands of farmers and partly in those of merchants.

If larger stocks are to be held by the private sector, the risks just mentioned have to be reduced. In the case of farm stocks, this could be done by an appropriate support price, set at a level that will prevent disaster but not encourage production. Trade inventories would presumably be hedged in the futures markets, where an official agency could participate as a buyer or seller (according to prescribed rules) to permit an adequate volume of hedging.[12]

Whether this agency should be national or international cannot be fully analyzed here; suffice it to say that price stabilization can—and under ordinary circumstances should—be profitable, at least over a period of years. Improved arrangements for food reserves should therefore not necessarily be viewed as a burden to be shared with other countries. The danger of leaving this task to an international organization is that prices may be fixed at unrealistic, politically determined levels.

Conclusions

If a national food policy is needed, it is not because the food markets are seriously malfunctioning. Thus, there is now evidence of a

[12] See Houthakker (1967). Some of the rules proposed there need revision in light of the discussions of flexible exchange rates in the early 1970s.

significant price elasticity on the demand side. More valid reasons for government intervention are malnutrition, especially of children in low income households, and excessive price fluctuations. It appears that malnutrition in the United States is largely confined to foodstuffs (milk, fruits, and vegetables) whose prices are kept artificially high by marketing orders and import restrictions. There is as yet little evidence that the food stamp program has had much impact on the nutritional status of the population or on the aggregate demand for food, but the program in its present size is still new.

Rather than dream about a comprehensive policy, we should perhaps concentrate on correcting those partial policies that impede the efficient use of food resources by distorting the market mechanism. In addition, measures to relieve specific malnutrition, and to facilitate the holding of adequate inventories by private operators, may be needed.

Food Policy: Implications for the Food Industry

Gary L. Seevers

This paper addresses the question of food policy from the standpoint of the domestic food industry.[1] My thesis is that the turbulent 1972–75 period has been unique and should not be used as a prototype of future problems. Several of the destabilizing influences during this period should be less significant in the future. Moreover, coming as it did after a long period of relative price stability, it caught both the food industry and the government off guard, and their initial responses often exaggerated the situation.

The food industry has been operating under conditions of greatly increased uncertainty since 1972. One source of additional uncertainty has come from food markets themselves: fluctuations in the supply and demand for food commodities generated short-term price volatility and concurrently contributed to doubts about the longer-term outlook. The second major source of new uncertainty derives from governmental policy: unexpected government interventions have become more frequent, and the absence of a political consensus on food issues leaves the most probable future policy in doubt.

There is an obvious interaction between market instability and government policy. Economic pressures in food markets enabled the government to discontinue obsolete production-control and export-expansion programs that had been widely criticized from an economic standpoint. However, the same economic pressures intensified conflicts between various interest groups and brought forth new government measures that added to uncertainty.

As one would expect, processes of adjustment have been set in motion in the food industry. Firms are altering business practices as the food industry searches for a new equilibrium. A similar search is also underway within the government, as the political system attempts to arrive at a new policy equilibrium. This process is slow and complex because it involves the resolution of conflicts between divergent interest groups and economic philosophies. In particular, conflicts between domestic and international objectives will be difficult to resolve.

The food industry's adjustment depends on some prediction about future government policy, but this depends on many imponderables including market developments. This state of affairs has caught the food industry in an intense national debate about proper food policy. Firms are making decisions with little certainty about the rules under which they will operate.

Market Instability

It is useful to think of the emergence of instability in two stages. The first stage became evident quite abruptly in late 1972, although its causes trace back somewhat further. Tweeten and Plaxico have succinctly summarized this change. The agricultural economy had been operating at about 5% below full capacity for many years. Given that the relevant elasticities for farm products are quite small, this margin was sufficient to provide a condition of abundance and price stability. Farm programs prevented excessive downside price fluctuations, and excess capacity together with ample grain stocks served as an effective cushion against large upside price swings. Then, over a brief period starting in 1972, export demand increased by approximately the amount of the excess capacity.[2] Along with a

Gary L. Seevers is a commissioner on the Commodity Futures Trading Commission.

[1] The term "industry" is used broadly to encompass the major segments of the industry—input suppliers, agricultural producers, handlers and processors, and wholesale and retail distributors. Although little differentiation is made among various industry groups in this paper, I believe producers have been the most affected by the instability in commodity markets followed (in order) by processors and handlers, input suppliers, wholesalers and retailers.

[2] The leading cause of the upward shift in export demand is

Table 1. Measures of Destabilizing Influences on Food Commodity Markets in the United States, 1964–67, 1968–71, and 1972–75

Measure	1964–67	1968–71	1972–75
U.S. grain yields[a]			
Corn	5.7	7.2	10.7
Wheat	2.2	6.2	6.2
U.S. economic fluctuations[b]			
Real GNP growth	1.9	1.8	4.1
Consumer price index	0.8	2.0	4.8
Grain trade (ex-USSR)[c]			
World imports	9.0	5.6	10.1
U.S. exports	9.3	8.3	11.4

[a] Average percentage deviation from linear trend of actual yields during 1955–75 crop years; several alternative measures of yield variability gave similar results.
[b] Average deviation from normal percentage increases of 4% and 3%, respectively, (calendar years).
[c] Average percentage deviation from 3-year moving average (fiscal years starting July 1).

strong domestic economic expansion, this brought equilibrium supply and demand into balance at a substantially higher relative price for food commodities in domestic markets.

The second stage, since mid-1973, has involved the instability of commodity markets operating in the absence of considerable excess capacity; greater price volatility is a predictable consequence. However, several extraordinary destabilizing influences compounded the problem during the 1972–75 period. (Table 1 gives comparisons with preceding four-year periods.) Domestically, grain yields deviated more sharply from trends, and the eruption of general economic instability caused greater fluctuations in domestic food demand. World market developments also had more influence on domestic markets. World grain trade and U.S. exports, even excluding USSR purchases, were more variable; the sporadic USSR purchases fostered chronic uncertainty in markets. In addition, certain aspects of price controls and the disruptions from the energy problem both contributed to instability and uncertainty during this period.

To a significant extent, domestic influences have contributed to the new market instability. Prior to 1972, domestic influences were relatively minor; fluctuations in export demand were the primary source of instability. In the future, it seems unlikely that the unique combination of destabilizing influences of the 1972–75 period will be replicated. Export demand is likely to become the primary source of instability again.

Private Sector Response

Market instability has created a general disequilibrium that is causing firms to make numerous adjustments.[3] These adjustments vary considerably from one part of the food industry to another. Although somewhat conjectural, several general directions of adjustment are apparent.

Firms are giving greater attention to collection and analysis of commodity market information, partly because previous relationships are less reliable and partly because outlook information has acquired greater value in decisionmaking. One indication is the new emphasis on the agricultural sector in private macroforecasting models; the desire to improve macroforecasts is one reason, but another is more requests from clients for agricultural forecasts. The acquisition of information on international commodity markets is more essential. For example, several firms now subscribe to weather reports on the USSR to monitor crop developments.

The removal of chronic surpluses has caused firms to shift emphasis from merchandizing their outputs to procurement of inputs. Forward contracting appears to be spreading for commodities that previously were sold primarily on a spot basis. One would expect firms to maintain more inventories to assure their input supplies, although high interest rates may have offset this adjustment. Inventory data are too unreliable to evaluate this possibility.

Volatile commodity prices have been an incentive for firms to increase their use of futures markets, for hedging fixed-price commitments and inventories, and to establish prices for subsequent cash transactions. For instance, the open interest in wheat increased 142% between the 1971 and 1974 crop years, and the proportion held by large, long hedgers

subject to some dispute. The devaluation of the dollar certainly had a pervasive influence, and increased USSR imports have been a specific source of new demand.

[3] The sharp increase in market instability raises many practical and analytical questions. How fast is adjustment occurring? Will it result in over investment? Will it eventually restore a more stable market environment? How does market instability affect the complex institutional relationships within the food industry? What is the impact on optimal firm size, enterprise diversification, vertical coordination, and the distribution of returns to managers with unequal capacity to deal with uncertainty? Will the disequilibrium created by market instability retard or induce technological progress?

increased from 51% to 65% (short hedging increased from 47% to 60%). Similar changes occurred in corn and soybean futures. Livestock futures are less widely used than major crop futures, but their use has also expanded, especially short hedging of cattle. Some cattle feeders have started using futures markets to lock in feeding margins.

Aside from price volatility, higher relative prices for food commodities have provided incentives to expand productive capacity. Accelerated capital formation is occurring, for example, in fertilizer production, transportation and handling of grain, and farm production. This necessary expansion will help avoid supply bottlenecks and increase future price stability.

A case can be made that the market instability of the past three years is greater than would exist if similar conditions were repeated. Under repeated but similar shocks, an economic system will learn to cope with the shocks, and the response will become less destabilizing over time. The sugar crisis of 1974 is a good example. For four decades the sugar program had imposed rigid price stability on domestic markets by isolating them from changes in world markets. Beginning in the early 1970s, world sugar stocks began to diminish because of rising consumption that exceeded production increases. The implications were not perceived promptly by domestic buyers, probably because they had become accustomed to a horizontal supply schedule for raw sugar. The protection and certainty provided to the sugar industry disappeared as world prices strained the sugar program beyond the breaking point. Initially, the sugar industry reacted by trying to build inventories in the face of a shortage. Rumors of large purchases by the USSR and certain oil-exporting countries contributed to panic buying, and sugar prices increased five-fold in a few months. However, two pieces of information became recognized. First, there was not an absolute shortage of sugar in the sense that sugar could not be purchased at any price. Second, it became evident that consumption would decline more than anticipated in response to higher prices. During this learning process, prices overreacted; subsequently, they declined and have become relatively stable. This pattern of overreaction to a reduced supply, sharp price increases, followed by fairly stable prices occurred in markets for many commodities in the past three years. In most cases, uncertainty over governmental response added to the overreaction. The point is that, after a period of overreaction and adjustment, reasonable stability was restored to markets. This behavior pattern warrants additional investigation, but it seems reasonable to expect that under similar circumstances the overreaction would become progressively less severe.

Governmental Response

The turbulence in food commodity markets has contributed to making food policy a major national issue. During the extended period prior to 1972, policy participants and impacts of decisions were much more confined. The foremost consideration of policy was the management of surpluses that were prone to exist at politically tolerable prices. Policy was oriented to commodities produced rather than foods consumed. Policy emphasized the income of producers and specifically the welfare of family farms, which accounted for the bulk of aggregate production. The international dimension of policy was mainly to alleviate domestic surplus problems. Food policy and issues tended to be resolved within the agricultural establishment.

As food policy gained national prominence, new participants became active in the debate. The agenda is no longer the primary province of the agricultural establishment (Paarlberg). Consumer interests have become ubiquitous in food price stabilization issues.[4] They have greater access and influence even though one can question whether they bring useful information to the decisionmaking process. Consumers have long been prone to complain about high food prices, but the sharp increases, particularly in early 1973, transformed a chronic concern into an acute one. Even though the rise in relative food prices occurred over a short period (table 2), it is a good bet that consumers' active involvement

[4] Organized consumerism actually began to appear much earlier, particularly in efforts to restrict the use of food additives under Food and Drug Administration regulations. The 1969 ban on cyclamate (an artificial sweetener) and the 1972 ban of DES (a feed additive) are prominent examples but not the only ones of this form of consumerism. Recent restrictions on pesticide use, air and water pollution controls, along with new health-safety requirements, are the consequence of the "quality of life" consumerism that began in the late 1960s. For many segments of the food industry, the impact of these peripheral aspects of food policy has been as significant on their operations as or more so than the market instability. Because of tensions among interest groups, governmental decisionmaking in these areas has been sporadic and an additional source of uncertainty.

Table 2. Annual Percentage Increases in Food, Nonfood and All Items in the Consumer Price Index Since 1967

	12 Months Ending in December			
	1972[a]	1973	1974	1975
Food	5.2	20.1	12.2	6.5
Nonfood	5.5	5.6	12.2	7.1
All items	5.4	8.8	12.2	7.0

[a] Compared with 1967 annual average.

in food issues will be a permanent consequence. They have played key roles in congressional deliberations on farm legislation since 1972.

Consumers may be the most important new interest group, but several additional groups have intensified their participation: organized labor, supporters of domestic food assistance programs, and the foreign hunger lobby. Participation in the policy debate during the 1960s was dominated by conflict resolution among producer groups and rising influence by agribusiness interests. That debate involved the role of government in managing surpluses; the new debate centers more on the allocation of limited food supplies among competing uses.

Priorities among policy objectives have been turned upside down. The level of farm income was an overriding concern during the 1960s, budget costs were a close second while food prices and international objectives were less prominent. Now, stability of farm income is important, and budget costs of farm programs are insignificant.[5] Food price stabilization and international objectives have much higher priority today and they have frequently come into direct conflict. For example, export-expansion programs that contributed to priority objectives prior to 1972 became inconsistent with the trade-offs after 1972. On balance, export policy has become restrictive rather than expansive compared with market-determined levels.

The resolution of the competing interests and objectives has frequently resulted in a whipsaw effect on major elements of the food industry. The lack of a consensus on policy issues has left the food industry with uncertainty about the stability of policy. This is best illustrated by pressures on grain export policy, a pivotal issue throughout the period.

Even after the costly experience with soybean export controls in mid-1973, there was major pressure to place controls on wheat through the following winter. By the spring of 1974, the prospect of bumper crops and falling grain prices eliminated consideration of controls. However, bad weather steadily dimmed crop prospects through the summer, prices rose, and export restraints were again on the policy agenda. A system of day-to-day monitoring and approval of large sales was launched, sales to the USSR were restricted to minimal amounts, and consultations with other countries led to "diplomatic" export restraints. The monitoring system was in place only a few months until grain prices fell rather sharply again. Pressures built to abandon any form of export restraint, which was done in early 1975. Only a few months later, however, new USSR purchases triggered steps to restrict exports once more. In a twelve-month span, the government intervened to restrain exports, acted to discontinue all restraints, and then intervened again.

The ability to predict government actions has become an important decision variable in the food industry. Fortunately, government policy is capable of adjusting to new circumstances, and some signs of consensus are emerging. Judging by revealed preference, the nation's food policy represents a sharp departure from the past.

There is a policy of large domestic food subsidies. Low income families receive several billion dollars annually through the food stamp program. Benefits are indexed to retail grocery prices, and participation varies with swings in economic activity. When combined with other federal food assistance programs, federal outlays are equal to 4% of retail grocery expenditures.

The commitment to food aid has been reaffirmed. P. L. 480 grain shipments are expanding modestly, and the U.S. share of world food aid is returning to past levels even without domestic surpluses. Perhaps more important, the distribution is being redirected to meet humanitarian objectives through congressionally-initiated provisions that set minimum percentage requirements for humanitarian aid, in contrast to "political" food aid. Beginning in 1969, as foreign-aid funding diminished, food aid began to be used in more

[5] Domestic food programs have become a big ticket budget item, partly because of higher relative food prices. In fiscal year 1970, budget outlays on farm income-support programs were $4 billion and domestic food programs were $1.6 billion; in fiscal year 1975, farm programs were $0.6 billion and food programs were nearly $7 billion. P. L. 480 outlays were comparable in both periods.

overtly political ways. It was first used in Indochina as a source of funding as other forms of foreign aid became tighter. Once the food-aid tool was discovered, it became widely employed for political purposes until dissatisfaction with this use of food caused congressional restrictions. In other areas of foreign food policy, it is evident from numerous policy statements that the administration attaches a great significance to food in the conduct of foreign policy. The combination of specific proposals and actions to deal with world food problems constitutes a rather ambitious program.

Periodic interventions to restrict exports or to allow more imports (mainly of dairy products) have had very disruptive market effects. The limitations of using this approach to achieve domestic objectives are many. Such steps are often contrary to a liberal trade policy; actions tend to be disruptive not only to domestic markets but also markets abroad. Even if only domestic objectives are considered, the lags between problem recognition, making a decision to act, and the impact of the action are sufficiently long that the effect on domestic markets is often untimely. As the problems with ad hoc actions to influence trade flows are recognized, the propensity to use trade measures for short-term domestic purposes has diminished. The recent agreement with the USSR should help remove one persistent pressure for periodic export controls.

The most constructive way to provide more stability in commodity markets would be to liberalize agricultural trade on a multilateral basis. Johnson has discussed the implications of rigid internal price stabilization policies in some countries on price instability in other countries. Signals of worldwide surplus and scarcity simply are not permitted to be transmitted to a large proportion of the world's producers and consumers. Since the United States accounts for much of the open markets, our food industry must adjust to global fluctuations to a far greater extent than would otherwise be the case. Unlike the pre-1972 period, when the average level of protection was the dominant problem, insulation from changes in world markets has become the dominant problem under the new circumstances. The current round of trade negotiations is an opportunity to focus on both problems, although progress will be slow at best.[6]

Unresolved Issues

Food policy may be taking shape in certain areas, but it remains highly unresolved in other areas that have important implications for the food industry. One area is grain price supports. How high should they be? Should they take the form of direct payments to producers, or floors under market prices? According to provisions in the Agricultural and Consumer Protection Act of 1973, which link price supports to the parity index, target prices for the 1976 crops will increase about 11%. However, the supports still will be sufficiently low, so that for all practical purposes the food industry will continue to operate without government price supports. Based on past experience, it is clear that, if price supports were to be set high enough, stability could be restored quite easily, but this would reactivate problems similar to those of past farm programs. The costs of attaining stability through higher price supports almost certainly would be quite high. This does not preclude modest increases. Useful guidelines have been suggested by Robinson, who also recommended that the implicit grain reserve system in current legislation could be improved by raising the spread between acquisition and resale prices. This approach would continue the market-oriented policies that have evolved over the past twelve years.

A second possibility is an explicit system of government grain reserves designed to stabilize prices, rather than the current system, which is only a back-up to price supports. The case for a purposeful reserves policy seems quite convincing. Conceptually, a reserves mechanism could maintain market prices within a prescribed band and provide at least three potential benefits. (*a*) Greater stability will reduce income transfers between producers and consumers and presumably the anxiety that goes with such transfers. Whether grain producers or users would benefit is unclear in the theoretical world of consumer and producer surplus (Turnovsky). (*b*) Steep rises in food prices can have adverse macroeconomic externalities that are not necessarily offset when prices decline (Okun). (*c*) Reducing price uncertainty will lead to more efficient allocation of resources, particularly at

[6] The recent bilateral grain agreements with two state-trading nations (USSR and Poland) will be contrary to trade liberalization objectives if they proliferate. Being bilateral, they are inconsistent with the most-favored-nation principle. They could also introduce new rigidity into trade flows. For example, these two agreements restrict discretionary purchases to a narrow range of only 8 million to 11 million tons per year.

the producer level but also elsewhere in the food industry.

In order to realize these benefits, the system must be designed so that it actually operates to stabilize prices. Reserves should be insulated from political pressures that would cause untimely release and acquisition. This would be a major advantage of a purely automatic system based upon decision rules. Recent analytical work on appropriate rules is helpful in this regard but, in my judgment, is not advanced to the point of being workable. A purely discretionary approach, in addition to being vulnerable to political pressures, would require improvements in worldwide crop intelligence in order to successfully stabilize prices within a reasonably narrow band around a long-run equilibrium price.

In weighing the costs against the benefits, it is important to consider adverse ramifications beyond easily measured operating costs. The system should be designed to minimize the substitution of government for private stocks in the United States. It should also take account of similar disincentives abroad, including neglect of agricultural investment in developing countries.

Assuming the United States is unwilling to resume its pre-1972 practice of holding reserves de facto for the rest of the world, a unilateral system would have to include one of two features. It would have to either limit access to reserves (e.g., only for food aid), which would reduce its stabilizing benefits, or incorporate a commitment to manage total export supplies in order to keep fluctuations in domestic prices smaller than export prices. The latter approach could be achieved with quantitative restrictions or, more efficiently, with export taxes and subsidies. It even has been argued that the United States should manage grain export supplies in order to exploit its short-run monopoly position in certain markets, but this would be inconsistent with a liberal trade policy and raise other objections.

Many of these difficulties could be overcome with a multilateral system that would force other countries to share the costs of reserves in relation to the benefits they receive. A proposal of this type by the United States is currently under consideration. However, other countries have been reluctant to confine discussions only to reserves since they want to incorporate other variables along the lines of a conventional commodity agreement. The design of a reserves system consistent with other aspects of policy is more complex than the idea seems on the surface. In particular, proposals to simply attach a system onto present farm programs seem to give too little regard to the international ramifications of domestic grain reserves.

A third unresolved issue has to do with data adequacy and statistical policy in both the food industry and the government. Increasingly, the private sector is required and expected to produce data that it may not, in fact, have available even to itself. Serious deficiencies have been revealed in the information of firms and especially of industry-wide data. Public demands for all kinds of information are sure to rise in the future, and the food industry's capacity to produce and interpret it must expand. This raises questions about how publicly accountable private firms should be required to be. Numerous deficiencies have also appeared in the government's statistical programs. Improvements are being made or are under study, but much remains to be done. Improvements in food policymaking will be contingent on better information systems to a greater extent than is often appreciated. The government also needs to give higher priority to sound procedures for making and announcing food-policy decisions. Unnecessary market disorder can arise from careless internal procedures, announcement of decisions, and release of market-sensitive information. The tradition of the U.S. Department of Agriculture in this area needs to be encouraged and extended to other points where food policy questions are addressed.

Conclusion

The food industry has adapted to the exceptional period of 1972–75 in a variety of ways, including investments to expand productive capacity in response to expanded demand. Government policy has likewise responded to the switch from relative surplus to relative scarcity, although more slowly. New participants have entered the policy debate, priorities have changed, and different policy measures have replaced those that became obsolete. The search for a national food policy has yielded tentative consensus in a few areas. It is far from complete, however, particularly regarding the stabilization of grain markets.

From the standpoint of private planning in the food industry, knowing what food policy

will be may be as important as its content. Food policy needs to have durability and consistency. If a particular policy's expected life is short, efficient planning within the food industry will be inhibited. Uncertainty over policy or frequent changes affects production and investment decisions just as market instability does.

One major need is to be able to upgrade the quality of decisions that are made regarding food policy. This will require improvements in information systems and diligence in handling market-sensitive information. But it also will require that policy not try to become overly ambitious in its scope and content. It will be wise to concentrate on the strategic issues, such as the merits and methods of grain price stabilization, rather than to overload the food policy agenda.

Discussion

Daryll E. Ray

Seevers' paper focuses primarily on the sources of recent instabilities in the food markets and initial private and government reactions to those instabilities. His thesis that the turbulent 1972–75 period should not be used as a prototype of future food industry problems is of interest, but of more concern is the market environment that can be expected and policy propositions consistent with the future environment.

Seevers seems to imply that since future turbulence in food markets is unlikely to be as severe as in the last three years, there is no urgency in reevaluating our food and agriculture policy. While general policy options are mentioned, no recommendations are made, and the status quo seems to win out by default. Rather than critique Seevers' chronicle of past food industry tribulations and government errors, my discussion centers more on policy reformation.

Orientation of Food Policy

As suggested by the National Planning Association, public policy for food and agriculture must be sufficiently flexible to handle a wide range of future market eventualities. To begin with, the foresight to predict accurately the relative growth rates in supply and demand of U.S. agricultural products in the years ahead is not available. In the shorter term, continued price fluctuations due to the low levels of U.S. and world grain stocks, year-to-year weather variability, and the extreme inelasticity of grain demand is expected. Hence, our food policy must be capable of handling year-to-year shortages and surpluses about a long-term trend of either falling or rising real prices for food.

In the following discussion, it is assumed that the objectives of a food policy are (*a*) to assure domestic consumers of ample food supplies, (*b*) to provide a degree of income protection to farmers from plummeting prices due to overproduction, (*c*) to modulate extreme price fluctuations and the attendant shocks to consumers and producers—especially livestock producers, (*d*) to encourage expansion of dependable export markets, and (*e*) to provide food assistance to those in the United States who cannot afford an adequate diet and to assist in international famine relief and agricultural development.

The challenge is to develop a policy framework appropriate for achieving the objectives. The Agriculture and Consumer Protection Act of 1973 protects neither farmers nor consumers from market contingencies (Ray and Tweeten). Governmental actions outside the Act have been disjoint and counterproductive. In the remaining space, a suggested policy framework is briefly outlined.

Price Support and Stabilization

As Seevers points out, price supports are set so low in existing legislation that for all practical purposes the food industry is operating without effective supports. In November 1975, target prices were 44% of parity for wheat and corn and loan rates were 29% of parity for wheat and 35% of parity for corn. With the increases in agricultural productivity over the years, full parity prices are obsolete, but parity percentages as low as implied by current target prices and loan rates would spell disaster for production agriculture. To effect the efficient short-term use of resources and longer-term investments in agriculture, farmers must have some price and income assurance. Target prices are a convenient means for supporting income especially if price declines are only periodic. To provide income protection, target prices must be set at reasonable levels. Due to the large input price increases in 1973 and 1974 and gyrations in yields, the target price levels specified in the 1973 Act need to be modified (Ray). Target prices for

Daryll E. Ray is an associate professor of agricultural economics at Oklahoma State University, Stillwater.

Journal article 3106 of the Agricultural Experiment Station, Oklahoma State University, Stillwater.

1976 could be specified at levels that reflect a large share, say, 80%, of production costs on efficient-sized commercial farms, including a cash-rent land charge. Hence, only part of land costs would be included in 1976 price levels. To avoid validating further escalation of land prices, annual adjustments after 1976 could be based on changes in nonland-operating costs of producing individual crops. Individual farm acreage allotment levels should be recalculated to reflect the crop acreage mix on the farm during 1974–75.

Production control provisions should remain a part of the policy framework. But production control should only be used to cope with chronic excess supplies. Policy administrators should not be allowed to offer voluntary set-aside until reserve (nonpipeline) stocks exceed target levels of 30 million tons of feed grains and 400 million bushels of wheat. When needed, set-aside levels should be calculated so market prices would be near but not exceed target prices with expected yields and demands. Target prices would pick up any price slack should yields be higher and exports lower than expected.

Although income protection must be upgraded, the first priority in food policy must be to implement a purposeful reserve stock management program to even out year-to-year supplies and to reduce short-term price variability. Unlike the 1950s and 1960s, its central purpose would not be to support prices and farm incomes. Target prices and set-aside would be used for that. Rather, the reserve mechanism would be used to help modulate extreme price fluctuations.

The acquisition and release prices for altering stock levels do not need to be fixed but could slide as stock levels change. Loan rates and release prices should approximate the marginal value society attaches to incremented changes in stock levels. In times of zero or low contingency reserves, the acquisition price should be set sufficiently high to reflect the value of accumulating stocks to help combat future sharp increases in prices. Loan rates might even exceed target prices under extremely low stock conditions. As the levels of stocks increase, the need or marginal value of more reserves declines, and so could the acquisition price or loan rate. Under such a plan, loan rates would eventually decline to below the cost of producing the commodity.

Market prices at which stocks are released could also be based on value of the stocks to society. When stock levels are low, stocks would only be released in times of very high prices. The foregone benefit or protective potential of releasing a unit of stock declines as the stock levels increase. Hence, there would be an inverse relationship between the level of stock and the release price. Sharples and Slaughter have advocated using the marginal value concept as a decision criteria and are working on making the concept operational.

The following stock levels, associated loan rates, and release prices illustrate approximately how the decision criteria would operate. Announced loan rates could be 110% of target prices when contingency reserve stocks (exclusive of pipeline or working stocks) were 0 to 15 million tons of feed grains and 0 to 150 million bushels of wheat. With reserves between 15 and 20 million tons of feed grains and 150 to 250 million bushels of wheat, loan rates might be 80% of target prices. Loan rates could be 70% of target prices with reserves between 20 and 35 million tons of feed grains and 250 and 400 million bushels of wheat. After feed grain and wheat reserves, exclusive of pipeline and working stocks, have reached 35 million tons and 400 million bushels, respectively, loan rates might fall off to less than one-half of the target prices or be completely inoperable. The sliding loan rates would tend to encourage further stock accumulations only in times when stocks are inadequate.

To illustrate stock release criteria, stocks might only be released when market prices exceeded 150% of target prices if feed grain stocks (exclusive of working stocks) were 0 to 15 million tons and wheat stocks were 0 to 150 million bushels. The minimum release price might be 135% of target price if reserves are between 15 and 20 million tons of feed grains and 150 and 250 million bushels of wheat. With feed grains and wheat reserve levels between 20 and 35 million tons and 250 and 400 million bushels, respectively, the minimum release prices might be 120% of target prices, and with higher stock levels the minimum release prices might be 110% of target prices. Under no condition would stock sales be allowed to depress prices below target prices. Also, there would be no government intervention in the markets as long as market prices remained between loan rates and stock release prices. The decision rules must be known by all involved—grain and livestock producers, consumers, grain traders, and importers—and must be followed explicitly by the government.

The stocks do not have to be in the physical possession of the government but could remain at the farm level (Tweeten). The government could pay farmers to store the commodities put under loan. Farmers would be directed by the government to place grain on the market when market prices reach release levels. In addition to the storage payment of perhaps 20¢ per bushel per year, farmers, not the government, would realize the price increment between the loan rate on this grain and higher release price (less interest charges). The memory of low prices associated with huge government stocks in the 1950s and 1960s is too vivid to expect farmers to support a grain reserve without inducements.

Food Shortage Syndrome

There is sufficient concern that the demand for agricultural products will press ever harder on supply so that efforts to expand the production potential of agriculture should be considered. Federal expenditures for agricultural research here and abroad could be expanded. Consumers should be made more aware that they, not farmers, benefit from the generation and adoption of improved agricultural technologies. Cost-sharing programs to upgrade, reclaim, and conserve agricultural lands could be revitalized and perhaps even undergo a wholesale expansion.

Our primary responsibility to less developed countries in the food area is to help them develop a sound and productive agriculture of their own. Considerably more funds and technical assistance must be provided to help stem the growing gap between agricultural production and food needs in less developed countries.

The primary objective of foreign food aid should be to relieve hardships created by serious production shortfalls as a result of natural disasters. Ongoing food-aid shipments should be allowed only as part of a comprehensive plan to upgrade the productive capacity of the recipient country.

Domestic food aid has become an important part of our food policy and will continue to be in the future. Our commitment must be to better focus our domestic food assistance programs on those that truly cannot afford to purchase an adequate diet in the market place. Taxpayers should not be expected to buy food for those who could otherwise afford it, and eligibility rules for the food stamp and other programs should be deliberalized, as appropriate, so that they do not.

Risk Management in Commodity and Financial Markets

Roger W. Gray

Having been asked to focus upon the problems outside primary agricultural production, and with the additional advantage of our early look at the Barry-Fraser paper, I have chosen to emphasize certain institutional factors in my approach. Recent events have highlighted the transition from institutionalized governmental risk bearing in the commodity sector back to the marketplace, as well as numerous problems and adaptions associated with the transition, including the emergence of a strong international oil cartel, proposals to counter this with other cartels, and a renewed interest in food reserves, as well as international commodity agreements. Concomitant with unsettled commodity prices have been massive disintermediation in the mortgage money market and a serious shrinkage in the availability of private equity capital. Mention of the collapse of real estate investment trusts and of the financial plight of New York City serves only to lengthen the list of horrors from which I must attempt to shrink in some orderly fashion. I shall retreat mainly to the confines of commodity price problems and the organized futures markets to see what has been done or could be done in that area, but I shall also venture a suggestion or two outside the commodity area.

The Role of Government

It is worth remembering that the role of government in commodity price determination had affected not only primary producers but merchants and processors and even consumers as well and had affected not only agricultural products but silver, gold, petroleum, etc. Processors in a number of industries had grown accustomed to reliance upon stable raw materials prices under government programs and had given little or no thought to hedging strategies in futures. As recently as 1970, some major cotton mills made no use of futures and had no expertise in the area. Prior to March 1967, silver users had been presented with pegged prices for many years, as of course had gold users until last year. Domestic beet sugar processors, with the 1963 exception, had dealt with essentially stable prices until the Sugar Act expired last year. The price support programs for grains had a similar effect, and the export subsidy that was maintained even in the face of massive Soviet buying in 1972 enabled grain firms to remain uncovered on sales and thereby delayed the reflection of this demand in the marketplace. Even without the Agricultural Act of 1970, which intended a transition to market prices, the transition would have been wrought by forces that wrenched prices into a free market orbit, anyway.

Meanwhile, the 1960s had seen the development of futures markets in the livestock area—one major agricultural segment that had not been subject to governmental stabilization programs. Thus, when the burden of risk bearing was transferred back to the markets in very recent years, there was a somewhat mixed readiness to take it up. Some exchanges, e.g., cotton, had become quite moribund; others, e.g., grains and livestock, had begun to flourish. Acquired hedging skills were present in some industries and not in others; some bankers were conversant with hedging while others were not; and probably no one anticipated the unprecedented range over which prices would move.

Market Response

In general, the established futures markets absorbed the vastly increased hedging load of

Roger W. Gray is a professor in the Food Research Institute at Stanford University.

1973 quite smoothly. Open interest in major grain and soybean futures rose to record levels, whereas cotton futures attracted high but not record levels of hedging. An interesting aspect of the composition of the open interest was the strong rise in long hedging. In wheat, cotton, and the soybean complex, reported long hedging exceeded reported short hedging for the year, whereas in corn futures long hedging averaged nearly as high as short hedging. Considering the unprecedented high hedging levels relative to speculation, the dramatic increase in long hedging reflects the extent to which the price rise rested upon real demand in the form of actual bookings. In the context of price risk, it was not so much shifted from hedger to speculator as from seller to buyer. Export contracts in particular undoubtedly accounted for much of the long hedging (although data are not available to show this), so much of the price risk was transferred overseas. Not only were speculators less involved than usual (in their proportion of aggregate futures holdings) and atypically more committed on the short than the long side in these commodities, but indications were that speculation neither caused nor benefitted from the major price rise. The comptroller general in a report to the Congress concluded from an examination of the trading of the fifty-five largest speculators and twenty-six largest hedgers in soybeans that neither group exerted significant buying pressure during a critical period of rapid price increase (U.S. General Accounting Office, p. 72).

Other major futures contracts attracted significant increases in trading in 1973, including live cattle, live hogs, sugar, cocoa, and copper, none of which, however, are export commodities. In perspective it appears that recent price uncertainty had led to a substantial increase in the demand for hedge protection, which had been accommodated at realistic price levels and to a significant degree between vertical segments within industries.

Some Problems

The foregoing brief assessment should not be taken to imply that the transition from governmental to private risk bearing during a period of unprecedented price change was accomplished without problems, nor that it is irreversible. A host of problems occurred, some of which still persist. Selected illustrations of these problems will reveal the need for and may suggest the nature of some remedies.

Consider first the case of a firm that did not hedge for lack of experience or even lack of any prior need for hedging. One large institutional feeding firm that contracts with schools and other institutions had enjoyed phenomenal growth for a number of years, then suffered catastrophic losses in 1973. The firm had never hedged in futures, and by virtue of a combination of years of stable food prices, skillful menu adjustments, and the ability to contract with suppliers had really not needed futures hedging. All three of these safeguards deserted the firm in 1973, and only during the post mortem did it begin to consider futures hedging. The remedy in this case is education, both in the general sense that management needs to understand futures markets and hedging and in the particular sense that such a firm needs to develop either internal competence or to contract with a firm that provides competence in operating a hedging program.

Another illustration concerns a cotton merchant who contracted with hundreds of farmers at high current prices and could not fulfill the contracts at harvest time after prices had fallen because he had not hedged. This appears to have been more a case of deliberate speculation than lack of hedging experience. In some respects, this resembles the sale of naked options and may require some regulatory oversight.

There have also been exposures against which no hedge was available for one reason or another. Selling livestock futures that would only lock in losses was scarcely an attractive alternative to speculation, even though the hedge was literally feasible. Another problem confronted the processor of specialty crops, such as canning vegetables, produced in competition with hedgeable crops. Contracting for the land at high prices created exposure for the processor, but failure to offer such contracts risked loss of supplies to competing crops. There may have been economic "cross-hedges" available to such processors or to barley malsters or to bakers, but the law did not regard these as bona fide hedging. Institutional adaptations may remedy such problems in time. For example, at least some banks now invoke the rule that acquisitions of feeder cattle will be financed only on a fully hedged basis, i.e., sales of cattle futures and purchases of major feed ingredient fu-

tures. Consideration is already being given to amending the legal definition of hedging to accord more closely with economic realities, the irony having been perceived in a situation that places no legal restrictions upon unhedged exposures but restricts the hedging of exposures.

Great financial risks were also imposed through official neglect of the sanctity of contracts. The embargo upon exports in the soybean complex in mid-1973, however seemingly warranted as a thumb in the dike against rising food costs, had a devastating impact upon holders of contracts to buy. The value of the long open interest in futures in the soybean complex declined by $400 million in seven days, and 50% of the outstanding export contracts were canceled. Apart from its failure to indemnify victims of such action, the U.S. government undermined confidence in its good faith in international commercial relations in such a precipitate edict. Overseas buyers subsequently abrogated some contracts to purchase cotton and grain from U.S. firms, thereby exposing the other side of the coin.

A little recognized aspect of the history of organized futures markets is the extent to which they have evolved as a solution to the "soft contract" problem. It is commonplace for private treaty forward contracts to prove to be either needless or useless. If the price does not change, the forward contract was not needed. If the price does change, the loser reneges and the contract proves useless. The "innovation" of the futures market had really nothing to do with "futurity," which had long since been embodied in the trading of all commodities, but rather with the establishment of a clearing house to keep all contracts "marked to the market" on a daily basis. Thus, the reason why futures contracts are not abrogated owes not so much to the integrity of the contracting parties but owes instead to the fact that there is no incentive to renege—the loser having already paid in his losses has no better alternative than the contract he holds. I point this out not for the sake of recording little-known facts but because it seems to me that international transactions may need to move toward a similar system. It does not matter if Thailand decides not to take delivery on a cotton futures contract that it entered into at higher prices, since it will already have paid the difference between yesterday's and today's prices.

The soybean embargo of 1973 and the 1975 embargo on grain sales to the USSR and Poland pose more fundamental threats. Futures markets can accommodate risk management only if the rules of the game are known and adhered to. The caprice of Henry Kissinger is not one of those risks the marketplace can long absorb, it being quite enough to cope with acts of God. There have been some signs, as in private trade support of grain reserves or buffer stocks, that the trade may prefer a situation in which the government assumes all the risk to one in which the government creates all the risk.

The Commodity Futures Trading Commission

Congressional hearings convened to investigate the performance of futures markets in the aftermath of the Soviet grain purchases, heard several allegations of malperformance in early sessions, but ultimately turned to the more constructive business of regulatory reform. The law passed in 1974 created an independent regulatory commission with considerably expanded and clarified authority compared to the predecessor agency in the Department of Agriculture. By including nonagricultural futures markets under its jurisdiction and by removing the authority from the Agricultural Department, Congress recognized among other things the incipient tendency for futures trading in financial instruments to be organized. At the same time that the law protects the existing jurisdiction of the Securities Exchange Commission and other agencies, it vouchsafes to the Futures Commission supervision of all futures trading in commodities and all other items and interests. Already, by having extended its authority to include futures contracts in foreign currencies, the Congress has nullified its own use of the word "commodity" in the title of the act. Other "items and interests" than commodities clearly meant just that.

Among the problems to which the Congress devoted considerable attention and the CFTC was directed to study are the definition of hedging, the terms of futures delivery with special reference to multiple delivery points, option trading, leverage contracts and other trading instruments, and participation in U.S. markets by foreign nationals or governments. Whether Congress in its perception of the priorities has been infallible is not so impor-

tant as its perception that the institution of futures trading is an important and growing one that needs more attention, better public understanding, and more enlightened regulation than it has received heretofore. That some agricultural economists writing in 1975 could have referred to the futures markets as a "nostrum" reflects all too clearly the need for better understanding. If improved coordination of economic activity and improved capacity for individual firms and industry segments to adapt to changing conditions are to be found, it will require increasing reliance upon and understanding of the opportunities afforded by organized futures trading.

The "Mortgage" Futures Market

The initial extension of the futures concept to "other items and interests" under the new law was the approval of a futures contract reflecting the prices of Government National Mortgage Association securities at the Chicago Board of Trade. This market had its genesis in factors that have given rise to futures trading in earlier circumstances, namely, (*a*) a perceived hedging need, (*b*) an active secondary market, and (*c*) problems arising from parties "walking away" from forward contractual obligations. The most conspicuous hedging need was that of the mortgage banker, whose modus operandi is analogous to that of a grain merchant in that both originate products that they intend to sell in a short time and which are meanwhile inventoried. The difference has been that the grain merchant originated products against sales of futures contracts, whereas the mortgage banker acquired unsold inventory. Certain government agencies had made available standby commitments for firm or optional delivery at fixed prices, and a dealer's market had emerged in GNMA securities issued against government acquisitions of mortgages.

This dealer's market had developed to the point where secondary (resale) volume exceeded the primary volume, and had devised various techniques for pricing the securities ahead. Essentially, these techniques were bringing the mortgage market and the capital market closer together. The intent of the Board of Trade was essentially to organize and extend the activity in this dealers' market under a standardized contract and rules. At the origination, the mortgage banker who entered into a "take-out" commitment with builders had to assume either the risk of changing rates or, if the rates were fixed in advance, the risk that the builder would walk away from the commitment. The hope is that, as through other futures markets, the "soft contract" problem can be eventually solved.

Remaining Legal and Jurisdictional Problems

The pending application before the CFTC to trade futures in short term treasury bills is being opposed by the SEC, as was the GNMA futures contract. This reflects a problem of long standing and also reflects the need for clarification of some basic definitions. Almost a decade ago, the Chicago Board of Trade sought SEC approval to open futures trading in common stocks, which was declined on the ground that it was a transparent effort to provide leverage in such trading contrary to Section 7a of the Securities Exchange Act, which was designed to control the extension of credit for stock transactions. In light of the fact that SEC had closed its eyes to the put and call options trading that had long existed for common stocks, the Board of Trade chose to seek approval to organize that trading instead of pursuing the application to trade futures. In consequence, a major new market emerged around a trading vehicle that is more cumbersome and less desirable than futures trading. Worse yet, the misapprehension that the leverage provided in futures trading somehow equates with the extension of credit has been left unchallenged. Other misconceptions were to follow. First, the firms that wrote naked commodity options created a problem that both state securities commissioners and the SEC attempted to solve by designating such contracts "securities," which they clearly are not in the history of case law nor in the common definition of a security. Subsequently, officials of the Federal Home Loan Mortgage Corporation sought an interpretation by the SEC that futures contracts for mortgages or mortgage-backed securities would be exempt from the act, only to reach the bizarre interpretation that while a GNMA security would be exempt, a futures contract calling for delivery of that security would not be. In other words, a security is not a security, but a nonsecurity is a security!

It is not clear on what grounds other than Parkinsonian ones the SEC presumed to object to futures trading in GNMA securities

after the CFTC had approved it, nor what the SEC objection may be to futures trading in treasury bills. It is clear enough that the congressional intent was to assign the responsibility for futures regulation to the futures commission, but it seems that the SEC may still have to learn the unequivocal fact that a futures contract is not a security. Fortunately, a strong agency now exists to help drive home the fact.

The new legislation and the commission that it created have several implications for risk management. Existing futures markets should be better understood, better regulated, and more widely used if the congressional intent is fulfilled. Problems of long standing, such as the Chicago delivery problem, are likely to be resolved under the new legislation. New futures markets, whether for commodities or financial instruments, will receive support wherever the commission finds evidence of economic need or potential usefulness. In short, the transfer of risk absorption from government to private hands, however partial or tentative it may be, is given a helping hand in the form of a government agency designed to strengthen the private institution most directly involved—the organized futures markets.

Some Remaining Problems

The risk-absorbing markets having enjoyed record levels of activity and having received a firmer official sanction than ever before does not mean that problems both internal and external to their operations will not persist. Internally, for example, we may well wonder how much waste is involved in a porkbelly futures market that looks more like speculators taking in one another's laundry than a true hedging market. How much more useful an allocation of venture capital would be achieved if a large fraction of porkbelly speculation could be diverted to hedging markets that attract too little speculation (of which there are several)? Or how large would the silver futures markets be if all the "tax spreading" were removed from their business, and how well warranted is such tax spreading? If tax advantage is justified to elicit venture capital per se, would it not be better to do this directly? Or to take another example, is there any danger that the fledgling mortgage futures market will only reveal how sheltered the specialized savings and loan institutions have been and perhaps will underscore the social desire for separating mortgage rates from the general capital market. Questions are also raised regarding the capacity of existing futures markets to take on additional contracts, especially in financial areas that are much larger than the traditional commodity areas, but the exchanges can probably devise methods whereby adequate market-making capability is assured (as with the Chicago Board of Trade's issuance of permits to trade GNMA futures).

External problems loom larger on the horizon than any of the above. Renewed efforts to organize commodity agreements or to organize cartels threaten a reversal of the recent transition of risk bearing to the private sector. Despite the overall dismal record of such agreements and the difficulties confronting cartel arrangements for most commodities, high energy costs reflecting the success of one cartel have evoked clamor from commodity-exporting nations to institute controls.

The food-price problem is perceived in many quarters as separable from other risky situations, especially since the entry of the Soviets into the world food picture. Some sort of official grain reserves scheme appears likely to emerge in consequence. While there is little doubt that governments can absorb risk in this area, the questions—at what costs in treasury outlays by which governments, at what costs in misallocation of resources in general—remain. From the standpoint of risk management in the commodity industries, the chief concern is that the terms of governmental participation be known in advance and be focused upon extremes of surplus or shortage to enable normal commercial risk management in the marketplace.

Structural Implications

Specialization in risk management, or developing optimal hedging programs, implies a large enough entity to justify expenditures for that purpose, and may thus appear to augur increasing concentration. Many commodity merchandising and processing firms, however, enjoy little scope for competition in technical efficiency and have long engaged in risk-management competition. The flour mills and soybean crushing firms have been sorted out, not so much according to manufacturing efficiency, which is reasonably uniform, but

more according to risk-management skills. There are also a growing number of firms specializing in developing and conducting hedging programs jointly with firms that are too small to afford their own research and risk-management capability.

By and large, of course, the futures markets have invigorated competition. Entry barriers are low, trading is conducted openly without serious possibilities of price discrimination, and the fragmented markets that antedated futures (and might otherwise exist) are brought together. At the same time, a larger individual trading. The many small potato dealers who leverage and protection afforded in futures trading. The many small potato dealrs who long opposed the futures market were rationally self-interested individuals who did not like seeing their isolated monopolies encroached upon. Similarly, the GNMA dealers at first opposed a futures market but, being more sophisticated, were also quicker to observe that they might make more money at a lower bid-asked spread on larger volume.

The most concentrated of any major futures market, among a number reported on as of 31 October 1975 by the CFTC, was corn futures at Chicago, where four traders held 48.5% of a very large long open interest. One can guess that this might be Cargill, Continental Grain, CPC, and Bunge or Cook, but apart from conjecture it is nevertheless a concentration ratio that is not high by other industry standards and a position that was established openly and competitively. Futures hedging also affords an alternative to vertical integration, although the two are not mutually inconsistent.

A final point that will not be developed at length here but that needs to be suggested in the context of risk management is that the major commodity firms that rely upon futures hedging are not so much risk averters, as the stereotype would have it, as they are risk selectors. They choose to earn their profits by skillful risk taking in "basis" relationships—relationships between cash and futures prices. Their rare exposure to flat price changes does not characterize them as risk averters—they simply take their risks in a different business. Their risks have been greater and their rewards higher since 1972 because they are skillful in risk management. Glancing at the other side of the coin, the professional futures speculator is typically a skillful risk manager as well, who scarcely fits the stereotype of risk lover. Risk management, as the organizers of this program recognized, is more apt terminology than risk aversion versus risk loving.

Risk Management in Primary Agricultural Production: Methods, Distribution, Rewards, and Structural Implications

Peter J. Barry and Donald R. Fraser

Price variability of agricultural products has increased greatly in the early 1970s owing to modified government programs for many U.S. commodities, reduced crop inventories, variation in world production, devaluation of the U.S. dollar, and expanded, unpredictable fluctuations in foreign demand. These increased market risks together with growing use of debt capital have substantially increased financial risks for many agricultural producers. Hence, there is serious need to consider added demands for risk-bearing and to evaluate relevant choices for reducing, shifting, or otherwise managing these risks.

This paper evaluates the feasibility and structural implications of relevant risk responses available to producing firms that differ by size and type. Emphasis is given to the value of managerial information in formulating uncertain expectations and to the producer's financial and marketing choices for managing price risks. Others (e.g., Houck, Robinson) have focused more exclusively on public choices for achieving price stability.

Market and Financial Risks in Agricultural Production

Table 1 contains annual coefficients of variation for monthly prices of selected commodities over the 1959–74 period. They reflect irregular influences on prices, since the data were modified to account for estimates of seasonal price patterns in the respective commodities (Barry and Maberly). The increasing effects of irregular influences on intrayear price variation are clearly evident for crops and to a lesser degree for livestock. Coefficients of variation for monthly prices of wheat, corn, soybeans, and sorghum increased greatly in 1973 and 1974. For cotton, the increase started earlier. Price variability also increased for calves and fed cattle. The variability for hogs appears high although it was exceeded in some earlier years. Coefficients of variation for annual mean prices are also rather high, indicating considerable price movement between the years of the time series.

This increased price variability is carried by a production sector with relatively small operations that have been declining in number and increasing in size since the early 1930s. Most farms are organized as proprietorships or partnerships. Even farms that have incorporated have done so for flexibility in tax and estate management and tend to remain small. Only a relatively few larger operations have attracted substantial equity capital from outside investors.

Table 2 summarizes average balance sheets and income statements of the U.S. farm sector on a per farm basis for selected years. The aggregate changes provide insight into the changing financial structure of individual firms. Most of the sector's financing has been provided by borrowing and retained earnings, although leasing is also important. The more rapid growth of physical assets, especially real estate, relative to financial assets reflects a reduction in asset liquidity. Changes in liabilities reveal further loss of liquidity. Total debts per farm grew by over 1200% between 1950 and 1975—greater than the growth rates of total assets and net income—with real-estate debt expanding more rapidly than non–real-estate debt. Larger operations with younger operators appear to be relatively greater users of debt (USDA).

Much of the sector's equity growth has occurred as appreciation in current market values of land and machinery. Capital leasing especially of real estate has also contributed much to the financial growth of producing firms. In 1969 about 37.5% of total U.S. land was rented with nearly two-thirds of the rented land operated by part owners (Johnson).

Income data reveal the narrowing operating margins, the increasing debt per dollar of net income, and the increasing importance of off-farm income, especially for smaller operations. In 1950, for example, it would have required 0.9 year to repay total debt with the use of all net farm income. In 1974 it would have required nearly three years. Part of this net income must be consumed by farm families implying even longer payback periods.

The higher financial leverage and lower liquidity experienced by many agricultural

producers magnifies potential losses of their equity and increases difficulties in servicing debts and other financial obligations from variable cash flows and reduced credit reserves. A vivid example of the effects of increasing market and financial risks has been the financial plight of many cattle producers and feeders. Large losses of equity in highly leveraged operations occurred during late 1973 and 1974 from severe price declines. Lenders experienced serious problems in loan repayment and security. They now require higher margins of equity with greater credit analysis and control. Sources of outside equity declined greatly and have an uncertain future.

Theory and Methods of Risk Bearing

In an uncertain environment, theory suggests that a decisionmaker will choose among alternatives with outcomes expressed by probability distributions so as to maximize expected utility (Arrow, Dillon). The utility-maximizing choice rests on the decisionmaker's strength of belief, on the relevant characteristics (mean, variance, etc.) of the expected probability distributions, and on his personal valuation of the potential outcomes.

Risk-averse behavior results when the decisionmaker exhibits diminishing marginal utility for increases in expected wealth. This feature of economic theory implies that the disutility of losses outweighs the utility of gains when gains and losses are of equal magnitude and likelihood. Hence, the risk averter will value a risky alternative at less than its expected monetary value. In effect the difference between the expected monetary value and risk averter's value is a risk premium or cost of risk bearing required to convert the risky expectation into one that is certain. The greater is the aversion to risk, the higher is the risk premium. Moreover, the level of risk aversion, and therefore the size of the risk premium, are assumed responsive to changing wealth, experience, age, and other relevant factors. Empirical evidence (Cohn et al.; Gordon, Paradis, and Rorke; Arrow) suggests, for example, that absolute risk aversion generally decreases as wealth increases, although the wealth responses of relative risk aversion have been less clear.

Insight on risk responses have been gained through a variety of decision theories. Many recent advances are related to portfolio theory emphasizing means and variances of items comprising the portfolio (e.g., Lin, Dean, and Moore). The mean-variance approach is applicable if a decisionmaker's utility function reflects preferences only toward mean and variance of expected returns or if he regards uncertain outcomes as normally distributed. For an agricultural firm, the choices in production, marketing, and finance generate a portfolio comprised of physical and financial assets. An efficient set of portfolios results from business plans providing minimum variance of expected returns for various levels of returns. An optimal choice among the efficient portfolios provides maximum expected utility.

Portfolio adjustments refer to changes in an optimal portfolio that result from changing risk aversion and/or shifts in the efficient set caused by changing expectations on levels of risk, rates of return, or wealth (Robison and Barry). The expectations on increasing price variability cited earlier imply a shifting set of efficient portfolios for the producer that yield lower levels of expected return for the same level of risk carried prior to the increase. Hence, a revised optimal portfolio for the producer with constant absolute risk aversion (Arrow) will yield lower expected returns, risk, and growth. Even more adverse effects will occur for producers characterized by aversion to risk that increases as expected wealth declines.

These portfolio adjustments to increasing price variability reflect higher costs of risk bearing and add urgency to the producer's search for effective methods of cost reduction. Several factors make it difficult for producers to directly bear these risks. Low price and income elasticities for many commodities subject to weather and other uncontrollable events provide an inherent setting for relatively wide price fluctuations. Moreover, producers have little capacity for influencing resource and product prices. Opportunities for stabilizing expected returns through product diversification have been limited by few product choices with negative correlation of returns and by the economic gains lost from more specialized production. Producers are often left to draw on their accumulated wealth in periods of adversity. Increasing wealth provided by capital gains on real estate probably has decreased many producer's aversion to risk. But many others lack the necessary wealth, and even when available, their wealth tends to be very nonliquid.

A more viable kind of risk response includes

the opportunities for transferring risks to other economic units more willing and/or better able to bear the risks through their wealth, their ability to pool risks over numerous and diverse activities, or their ability to spread risks over numerous claimants. Arrow suggests, for example, that the government can effectively pool risks and spread its costs of risk bearing over such a large number of taxpayers as to reduce these costs toward zero (ch. 11). Arrow further characterizes market perfection in transferring risks as the emergence of marketing institutions for freely insuring against any economically relevant event with premiums determined by supply and demand for the contingency claims. He suggests that, when the market fails to achieve an optimal state of risk bearing, society will to some extent at least recognize the gap, and nonmarket institutions will arise attempting to bridge it.

For price risks in agricultural production, only a limited and imperfect set of market and nonmarket methods for risk transfer have emerged. Since the 1930s, price and income variability in agriculture were indirectly met by various price, income, trade, resource, and inventory programs of the government. However, the price-supporting features of many of these programs focused more strongly on increasing the level of farm income rather than reducing its variability. As a result, these programs often stimulated growth in production capacity, thereby compounding problems of supply management and income stability.

Recent modifications in government programs have shifted a large portion of the risk-bearing function from the public sector back to the private sector. Moreover, within the private sector much of the risk appears to rest with producers as opposed to input suppliers, product handlers, and retailers. This withdrawal of the public sector as a major risk bearer in agricultural production shifts emphasis to other markets for risk bearing—namely, markets for managerial information, financing, and commodities.

Building Management Information

As price and income risks increase in agriculture, producers will value more highly flows of new market and financial information that update and improve their expectations on future events. Hence, there will be increased demand for education and for hiring various kinds of information services. The information problem is likely more serious for crop producers who rely greatly on government programs in formulating market expectations. Many are ill-equipped to utilize market reports on currency devaluations, droughts, contracts for foreign grain sales, forward and futures contracts, etc. Livestock feeders could also use provisions of government programs in evaluating cost and availability of feed inputs, but like other livestock producers, they were more self-reliant in processing information on livestock prices.

The capacity to acquire and use new information likely varies with the producer's size of firm and its relation to other firms in the food system. The family farmer is typically a general manager concerned first with production, then marketing and finance. The wide range of management responsibilities limits his capacity to continually absorb and process new information. He relies greatly on general research and education offered by the public sector or on more specialized counsel provided by trade firms and lenders. He is likely to experience costly lags in adjusting his operation to a riskier environment.

Larger producing firms have tended to specialize and decentralize the management functions, allowing the firm to embrace a wider range of managerial services than is typically found in smaller farm proprietorships. These features characterize all types of growing firms, although they are especially evident in operations amenable to more industrialized production with greater market coordination. Specialization and internalization of management and information activities are a form of size economy that is not well documented in research. Some observers (e.g. Moore and Dean) cite serious competitive difficulties for smaller, family operations that need increasing public assistance to develop information systems comparable to those of larger firms.

The relatively small size and competitive environment of most producing firms creates disadvantages relative to farm-related market firms in building information. The larger size, commodity specialization, and greater market power of many input suppliers and product handlers provide considerable capacity to collect and utilize market information, thereby improving their market expectations. These factors lower the market firm's costs of risk bearing and may modify market risks as they are transmitted through the food and fiber system.

Financial Responses to Risk

Financial responses reflect the capacity to accept risks in marketing and production or to spread these risks among those with financial claims on the firm. In larger corporate firms, the wide dispersion of ownership helps to spread business risks over a large number of stockholders. The total costs of shareholders' risk bearing declines with increases in their number and as their share of wealth that is invested in the business remains small. However, the smaller producing firms in agriculture have little capacity for this kind of risk reduction.

When most resources were produced on farms and little debt was used, the brunt of adverse events was generally absorbed first in family consumption, then in partial liquidation of assets, and finally in emergency borrowing. In today's agriculture, the sequence is nearly reversed. Family consumption levels have risen and become less sensitive to variations in annual income. Purchased resources and increased capital investment have brought greater use of debt capital. Larger proportions of farm sales are now obligated to debt servicing, although off-farm income has increased as well. Hence, agriculture's financial responses to risk are now largely expressed in liquidity management and are influenced by the marketability of assets, borrowing capacity, and by terms on borrowing and leasing that modify variability in cash flows.

These financial responses to risk are still largely regarded in terms of defense or rescue mechanisms to be activated only in periods of adversity. If excluded from the mainstream of the producer's financial planning, they are uncertain as to their reliability and availability when most needed. In a more uncertain market environment, it seems reasonable to bring financial choices toward the forefront of risk management. The object is to make the financial environment more stable and predictable, enabling the producer to develop more formally financial plans for countering risks in his marketing and production environment (Baker). A more stable financial environment that can carry a greater share of agriculture's market risks will in turn reduce the need for stabilization programs that disrupt the operations of commodity markets (Baker).

Bringing financial choices to the forefront of risk management is not a simple task. Consider the choices in liquidity management. The assets of most producing firms are generally dominated by land, machinery, breeding stock, and other fixed assets whose liquidation would be costly. Even crops and livestock being produced are nonliquid due to long production periods and attachment to land. Highly liquid financial assets are rarely in portfolios of younger, expanding operations due to their large denominations and high opportunity costs. Moreover, access to high quality investment information is more limited in rural areas (Brake).

Greater reliance has been placed on the producer's borrowing capacity as a source of emergency funds in meeting variable cash flows. Evidence has suggested that producers seldom totally exhaust their borrowing capacity, even though higher leverage appears profitable (Barry and Baker). This reservation of borrowing capacity implies its value as a source of liquidity whose use does not greatly disturb the firm's asset structure or production organization. However, reliance on credit liquidity shifts a substantial portion of the firm's financial control to its lender. It is the lender who appraises the borrower's credit, setting limits on size and terms of loans in accord with his institution's legal requirements, availability of funds, and his risk-liquidity preferences. The credit evaluation may be tempered by the loan purpose and managerial practices of the borrower that affect quality of loan security and prospects of repayment. But, agricultural producers' skills in demonstrating credit worthiness—accounting, financial control, and cash and capital budgeting—have been slow to develop.

Increasing the capacity of financial markets to distribute agricultural market risks requires close alliance between rural lenders and larger money-market centers and adaptation of loan programs to more directly confront uncertain cash flows. Over time, commercial banks and other lenders in rural areas have improved their linkages with financial markets through use of liquid financial instruments and better communication. Examples include increased transactions in federal funds and overline participations between commercial banks and the favorable reception of bonds sold by the banks of the Farm Credit System. Still, there is concern with improving the availability of funds to rural areas, especially through the banking system (Federal Reserve Board of Governors). Proposals have included the establishment of secondary markets and pooling

mechanisms for agricultural loans. These proposals probably need evaluation in terms of their effects on risk bearing in financial markets as well as their effects on flows of funds.

Some agricultural lenders provide for principal deferral or advance payments on indebtedness, although these are seldom central features of the loan program. In addition, many non–real-estate lenders prefer to finance farmers solely on an annual basis carrying unpaid debts over to following years until they are fully repaid. Such loan practices leave the producer fully dependent on the lender's availability of funds and provide little capacity for the producer to adjust his financial organization to changing market conditions.

To provide this adjustment capacity, consider first an optimal loan program in a completely certain environment. The borrower would prefer minimum cost leverage with a maturity structure of debt that is roughly in accord with the payback periods for the items being financed. The result would be a set of self-liquidating loans with the respective assets pledged as security. In the more realistic, uncertain world, there is need for enough flexibility to lengthen and shorten these debt maturities in response to variable cash flows, and still provide lenders with adequate security. Hence, credit reserves must be large enough to provide additional loans to meet financial obligations in periods of adversity and flexible enough to convert excessive short-term debt into longer-term debt. Moreover, the loan program should be designed to restore a more acceptable debt structure when adverse conditions have passed.

This approach to financing under uncertainty utilizes the principles expressed in the income bond—essentially a loan with variable payments on interest—although extended here to amortized loans. The loan agreement could stipulate that payments of interest and principal be contingent on the magnitude of cash flows from the firm's operations. Debt servicing would be expected to adjust downward in periods of reduced cash flow and upwards in more favorable periods. Targets on payment levels, equity, and other measures of financial performance could be based on the borrower's financial strength and projected repayment capacity. Variations around the targets could be constrained within tolerance limits that are mutually acceptable to both borrower and lender. Detailed financial projections with periodic review would permit effective financial control. Such a program would demand complete and longer-term commitments by both lender and borrower, but it would formally accommodate variable cash flows and would likely contribute to improved financial management in agriculture. Financial risks would not necessarily change for lenders who have customarily used short-term commitments to finance their agricultural borrowers over unfavorable periods. Lending risks might even decline as experience with these programs is gained.

Other financial responses to increasing risks also warrant brief attention. Formal insurance (life, crop, and fire) provides a low cost source of contingent liquidity. However, insurance markets are generally limited in scope of insurable events, in extent of financial coverage, and even in freedom of action for the insured. In real estate leasing, crop and livestock share rents have been common and will likely warrant even more attention for their capacity to share expected income variability between tenant and landlord. Longer term leases also help to reduce tenure risk, as does leasing from multiple landlords.

Market Responses to Risk

A producer's market responses to risk include combinations of inventory management and forward commitments on prices and production with other participants in commodity markets. Inventory management refers to production and storage policies that influence the timing and magnitude of the producer's marketings and therefore largely affect risk bearing within the firm. Forward commitments on prices and production transfer part of the producer's price and yield risk to forward buyers or other speculators.

Inventory management can reduce risk through greater flexibility and/or more frequent, sequential marketing. Flexibility provided by storage permits the producer to hold commodities for favorable price movements. Moreover, buffer stocks from which sales would occur when yields are short of expectations and to which additions occur when yields exceed expectations provide for income stability over a series of marketing periods. Sequential marketing results in price averaging over the marketing periods, providing greater certainty in price expectations.

A producer's opportunities in sequential harvesting and marketings for perishable crops are limited by similarities in growing seasons for most crops. Geographic diversification of production over areas with different growing seasons may help provide sequential marketing for larger operations. For nonperishable crops, sequential marketing is provided by investment in storage facilities with sufficient returns expected to cover investment and operating costs. While substantial investment in on-farm facilities for grain has occurred in the corn belt and other areas, producers have only recently begun to consider sequential marketing as a viable strategy. It is still common for producers to hold large blocks of commodities in hopes of favorable price changes. Increasing irregularity in price movements makes this practice quite speculative.

For livestock, greater frequency in marketing requires less seasonality in production and feeding programs. Sequential marketing appears common in larger cattle operations and in many hog operations, especially those with substantial investment in production facilities.

Forward pricing arrangements can be used together with or separate from the producer's inventory programs. Forward contracts generally consist of the producer's promise to deliver a specified volume of production at a designated time, place, and price. The contract may or may not be associated with a commodity futures contract. The forward contract eliminates the producer's uncertainty of the future product price for that time period by transferring part of the price risk to the forward buyer. In turn, the forward buyer may hedge his position with others to transfer the risk further. In any event, the risk-bearing function is transferred to others who can likely accept it at lower cost due to their larger numbers, diversified portfolios, skills in market analyses, or risk preferences.

However, forward contracting does not completely eliminate risk in the producer's expected cash flow due to uncertain expectations on the future level of production. Shortfalls in yields can force the producer into the cash market at harvest to cover his contracted volume of production. Price and yield risk are jointly treated in a conceptual model developed by McKinnon to derive optimal levels of forward sales and inventories of buffer stocks for primary producers. The contracting decision is based on expected means and variances of prices and yields, and the criterion for optimality is minimum variance for a given level of income. Hence, the optimum is formulated as the desired level of contracting in a producer's portfolio decision.

McKinnon's model shows how the correlation between an individual producer's expected output and price, together with relative variabilities of yield and market price, can jointly determine the optimal contract. The model provides the following decision rules: the greater is price risk relative to yield risk, the greater will be the optimal forward sale, and the more highly negatively correlated are price and yield, the smaller will be the optimal forward sale. Hence, forward contracts hold greater potential for commodities with stable yields and geographically dispersed production. In addition, the adoption of yield-stabilizing practices will contribute to higher proportions of product contracting.

The producer's yield risk is more serious in forward rather than futures contracts owing to their lack of secondary markets and low market liquidity. Hedges in futures contracts that become partially speculative due to changing yield or price expectations can be adjusted prior to maturity. Moreover, the yield variability in primary production suggests lower levels of optimal contracting for individual producers than for forward buyers who can pool production risks over numerous, geographically dispersed producers and who may more easily gain risk premiums in their pricing policies.

McKinnon's analysis also indicates how producers can combine individual buffer stocks with forward sales to jointly mitigate the effects of price and yield variability on the firm's cash flow. He further argues that farmer-held buffer stocks and forward sales are more effective than farmer-held buffer funds or merchant-held buffer stocks for stabilizing the income effects of variations in agricultural production.

The extent of use of forward and futures contracts by primary producers is difficult to fully assess. Periodic studies of traders in commodity futures contracts have indicated a relatively low incidence of use by primary producers and even then speculation appears more prevalent than hedging. Data on the extent of forward contracting are also deficient. USDA estimates suggest extensive contracting in commodities amenable to capital-intensive, industrialized production: broilers, turkeys, vegetables, sugar, milk, and citrus

(Manley and Reimund). Cattle feeding has experienced increasing contracting, and some hog producers have experimented with contracting. Contracting in major grains and cotton was low in the past, although increasing in response to greater price variability (e.g., Nichols and Sporleder).

Some kinds and qualities of commodities do not have suitable futures contracts for hedging. Sorghum futures, for example, have not had sufficient volume to support a hedge. Some cotton does not fully meet quality specifications in commonly traded cotton contracts. Even delivery dates on futures contracts may not coincide well with expected harvest dates for many producers. Producers with these problems must either hedge in other contracts that correlate closely with their commodity's characteristics, use forward contracts, or refrain from contracting.

Indivisibility in sizes of futures contracts interacts with optimal levels of contracting to impose size restrictions on volume of hedging to the disadvantage of small firms. Consider, for example, a commonly used 5,000 bushel corn contract together with 50% contracting and yield expectations of 100 bushels. One hundred acres of corn are required to provide for one contract. If corn acreage comprises about half of the crop acreage as is common on many midwest farms, then a farm unit of at least 200 acres is needed for a single contract.

Hence, contracts appear more suitable for larger firms in the production sector. Furthermore, farm-related market firms may have comparative advantages in contracting. Larger, more specialized producers and trade firms experience more frequent market contact, handle larger volumes of production, and have greater capacity to collect and process market information.

One method of extending the market advantages of larger trade and production firms to primary producers is through marketing agreements offered by marketing cooperatives (Black and Knutson). The producer essentially contracts to transfer the functions of product storage and sale to the cooperative. Pricing is accomplished through pooling of cooperative returns with a partial payment when the product is delivered. The balance is payable at the end of the cooperative's marketing season. Frequent marketing by the cooperative helps to stabilize the producer's price expectations. Also, the cooperative's knowledge of commodity flows, larger size, and specialized management may even raise expected returns.

Interactions in Financial and Market Responses

It is reasonable to expect that a producer's market responses may interact with financial responses in developing a risk-management program. If expanding credit is important, the producer may adapt his level of contracting to accommodate his lender's preferences for the collateral and greater certainty of loan repayment provided by the contract (Barry and Willmann). For hedging with futures contracts, margin requirements in response to price changes through the hedging period require a flexible credit agreement. Buffer stocks may add further to credit by serving as loan security to lenders and providing greater assurance of product delivery to forward buyers. Hence, market choices that improve expectations on loan repayability may expand credit and/or reduce the producer's need for liquidity.

Structural Implications of Risk Responses

The feasibility of these risk responses appears to vary greatly with the producing firm's size, major enterprises, and quality of management. Nonetheless, several implications for size and financial and market structure of producing firms can be briefly explored.

Generally, success in reducing costs of risk bearing appears more likely in larger firms. Larger proprietorships and partnerships tend to have greater managerial capacity and easier access to commodity and financial markets for transferring risks. Hence, well-managed agricultural firms may find increasing opportunities for acquiring assets of other operators lacking the skills, temperament, or financial capacity to manage increasing market risks. However, the pace of such growth will depend greatly on costs of additional capital.

Implications for financial structure of producing firms depend largely on risk responses of capital costs, on modifications in financial markets to accommodate higher risks, and on the producers' financing strategies. Measuring the responses of capital costs to increasing risk is difficult in an industry comprised of

rather small firms with limited financial data who rely primarily on retained earnings and borrowing from rural lenders. Estimating changes in costs of retained earnings is nearly impossible to verify. Costs of equity capital for the few producing firms with stock traded on organized exchanges appear to have risen along with rising business risks in the early 1970s, but none of these firms attracted any significant amounts of new equity during this period. Interest rates on farm loans from the cooperative Farm Credit System, rural banks, and other lenders may increase to build reserves for expected loan losses, but these rates seldom vary among borrowers. The brunt of risk pricing for farm debt is expressed in terms of loan limits that differ among borrowers—a more inefficient and less effective pricing mechanism. Here, lenders' requirements for higher margins of equity, additional security, and other more conservative loan practices together with greater liquidity preferences by producers have added to the costs of using debt.

Hence, for most family-size operations, it appears that relatively greater costs of debt capital will initially prompt shifts to lower leverage in their liability structure. However, larger operations may grow relatively faster by reducing risks through choices in markets for information and commodities and perhaps by spreading risks with equity capital markets. The potential impacts of these risk responses on financing institutions are also important. As an example, the increased borrowing needed by larger producers will increase pressure on the size, organizational structure, and portfolio management of lenders both to provide the financing and manage the greater risk.

In commodity markets, increasing use of forward commitments to transfer price risks may significantly alter market structures for commodities that have been characterized by open market exchanges. The price controls provided by forward contracts could seriously distort the signals for resource adjustment and the distribution of rewards from production and risk bearing. More stringent terms on nonmarket linkages may also alter managerial control in agriculture. Control of decisionmaking for producing and marketing commodities could increasingly shift out of the production sector. So could resource ownership. Alternatively, group action by producers through cooperatives or other means of commodity pooling may retain decision control in the production sector and lead to prices at least partially administered by producer. In either case, the terms on which supply responds to price would be modified. So would the performance of agricultural markets.

In summary, risk management requires resource commitments whose costs likely vary by size, type, and organization of firm. Moreover, there may be important comparative advantages among farms and between farm and market firms in managing risks. This paper has focused primarily on risk responses in markets for managerial information, finance, and commodities for distributing risks. Yet the public sector is also a candidate for risk bearing, and clearly the costs of national and international programs stabilizing farm prices and incomes must be compared with the costs of other means of risk bearing.

Discussion of Research Implications

Clifford Hildreth

Having grown up in Kansas during dust storms and an undisguised depression, I am perhaps not quite as horrified by Gray's list of horrors as some younger colleagues might be. Unsettled commodity prices do not seem as hopeless as prices that have firmly settled near zero. However, I do share his and others' deep concern and their hope that economists can make useful contributions to the resolution of current difficulties.

Both Gray's and Barry and Fraser's papers have cited urgent reasons to consider adjustments to uncertainty at this time. Market developments have made government price guarantees irrelevant at a time when foreign demand has become more uncertain and more important. It is also a time when the high cost of capital and the greater need for debt financing make many firms particularly vulnerable. Uncertainties about our government's trade policies compound the difficulties.

These special needs seem to be accompanied by special opportunities. Emergence of problems may well have created some political flexibility. Cogently reasoned new proposals may receive more serious consideration than in settled times. Gray's citation of the broad mandate to the Commodity Futures Trading Commission might be taken as one indication.

I was asked to comment on research implications. First, let me express some views on theoretical developments and then some conjectures on possible applied projects. As indicated by Barry and Fraser, many economists believe that the most promising current theoretical approach is one that assumes the decisionmaker acts to maximize his expected utility. I concur. However, one has to realize that, despite significant advances in the past two decades, almost all expected utility formulations of economic problems involve highly restrictive simplifying assumptions. This does not mean that applications should not be made. It means that applications have to be made with considerable judgment and conclusions treated as tentative unless strong verifying evidence can be adduced.

For example, many logical objections have been raised to mean-variance analysis, and these seem generally convincing. However, there may be many situations in which mean-variance analysis may reveal the most important considerations in a contemplated application in simple, accessible form. The situation reminds me somewhat of discussions of a Marshallian partial equilibrium analysis a few decades ago. Partial equilibrium analysis is logically incomplete and is sometimes misleading but, when applied with care and judgment, often gives a good initial grasp of a problem and is still usefully employed. Similarly, I believe mean-variance may often furnish a useful start for analyzing a problem, but possible shortcomings should be carefully considered before conclusions are regarded as firm.

To strengthen applications, much further research is needed on the nature of relevant utilities and personal probabilities. Barry and Fraser cite studies that suggest that decreasing (with wealth) absolute risk aversion may be typical of individual utility functions. This has generally been presumed, but we need to continually seek further hints and evidence on such questions. If the presumption is generally true, are there recognizable exceptional circumstances? Does it apply to both private decisionmakers and corporations? What about other kinds of institutions?

A simple example of a theoretical proposition that can be misleading if the special assumptions under which it was derived are not borne in mind is the oft-quoted assertion that "the risk averter will value a risky alternative at less than its expected monetary value." This conclusion arose in models in which the decisionmaker was assumed to have fixed initial wealth. It remains true if the decisionmaker initially has an uncertain prospect that is stochastically independent of the risky alternative being considered.

However, if the risky alternative promises

Clifford Hildreth is a professor of economics at the University of Minnesota.

to reward the risk-averting decisionmaker under circumstances in which his wealth would otherwise be relatively low and penalizes him under more favorable circumstances, it will be valued at more than expected monetary value. A familiar case is property insurance. The return is risky—many people pay premiums a long time without receiving anything, the expected money return is negative, but many risk averters buy property insurance because the prospective positive return occurs under circumstances in which the need is great. Typical commodity hedging is another example.

A decisionmaker with really certain initial wealth could hardly exist in the real world and I believe relations between initial prospects and new alternatives are typically important so such relations have been emphasized in theoretical models I have begun to consider (e.g., Hildreth).

Particularly interesting cases of risk averters being willing to pay more than subjective actuarial value occur if there is an event that would be harmful to one decisionmaker and beneficial to another. If the parties hold the same subjective probability for the event, then the first decisionmaker is willing to pay more than actuarial value for a contract under which the second party compensates him if the event occurs. The second is willing to sell at less than actuarial value. There is a traders' surplus somehow to be shared.

A closely analogous but slightly more complex situation would occur if a vegetable grower who did not have access to a futures market sold forward to Gray's institutional feeding firm that failed to hedge supplies. Both parties would stabilize income prospects and, if they were risk averters, the seller would be willing to sell below the break-even price and the buyer willing to buy above. The situation seems worth distinguishing from one in which each party sells to a speculator who charges a risk premium. When the original parties deal directly, it would seem more appropriate to refer to "cancellation of risks" rather than "passing of risk from seller to buyer." If there were many growers and feeders who dealt through a futures market rather than individually, the situation would be essentially unchanged. To the extent that markets can be organized to bring together traders who have complementary risks of this type, speculators and risk premiums are not needed.

In applied research, a major need is to supplement recent theoretical discussions of contingent commodity and contingent money markets with research into the feasibility and potential value of specific possibilities. One example, the possibility that futures markets might offer contracts in which the quantity delivered is dependent on weather experienced, has been suggested by Sandor. This prospect could be investigated along with research on other extensions of futures markets suggested in both papers presented today. Extensions to new commodities, new traders, and new geographical areas are contemplated.

Concerning new traders for existing markets, it is widely said that, for agricultural products, the volume of forward trading is much greater than futures trading. This does not seem necessarily bad, but the possibility that extended futures trading would be beneficial deserves careful study. Gray indicates that assured compliance with the agreed terms was the main incentive in the establishment of futures markets. This is clearly of continuing importance, but I wonder if the fact that the futures market exposes each trader's offer to many potential traders and thus brings about some general balancing of supply and demand may be of comparable importance.

As things stand, both of these advantages of a well-organized general market may be lost by forward traders who have special needs or who are geographically less accessible. With modern computers and communications, I wonder if futures markets could usefully expand by offering both buyers and sellers a wider variety of more specific contracts, providing more frequent and specific delivery dates, more indicators of quality, and a larger array of possible delivery points. Some contracts might have buyer's options, others seller's options, and still others might be quite specific on both sides.

I cannot, of course, presume to know how much forward trading that is now individually negotiated could economically be encompassed in organized futures by such extensions. It does, however, seem to me a very worthwhile area for research. In addition to the advantages of reinforcing the integrity of contracts and offering each trader more exposure to others, such extension should make futures quotations still more representative of general demand and supply conditions and, by increasing both volume and potential volume, make short-term movements less influenced by actions of large traders. It

seems likely that extension of markets in this way would place a severe strain on pit trading and that a system of computer matching of offers to buy and sell under specified terms would likely be needed. To progress in such investigations, descriptive studies of current forward trading is needed as an early step.

Gray's suggestion concerning new geographical areas for trying to extend the advantages of futures trading to international markets is very appealing. Difficulties such as governments of major trading countries abound, but the advantages to all concerned in having assured access to a market that represents current needs and costs reasonably well should be very persuasive if careful research verifies them and they are coherently explained.

I also find the Barry-Fraser discussion of alternative risk-abating devices for primary producers quite stimulating and believe their account contains guides for interesting and productive research. Projects to find risk-complementary or at least risk-independent enterprises to combine on farms should be challenging. Attempts to attract nonfarm industries whose activity would not be tied to local farming receipts would be good for the entire regions concerned, as well as furnishing nice labor hedges for small part-time farmers.

Diversified enterprises and/or combined small farm, off-farm activities may have aesthetic appeal for some people. Formal economics deliberately ignores the technology of consumption and the utility of production. Perhaps much is sometimes lost in this way. Such a possibility might well be explored in researching these alternatives.

Another Barry-Fraser proposal, the design of financial instruments that would provide the kind of flexible payment loans they envisage, sounds to me like a very worthwhile and challenging enterprise. The inverse correlation between need for loans and eligibility as determined by existing financial institutions has been frequently noted. Making credit available when needed while protecting both parties will certainly be productive if it can be achieved. Perhaps some government participation will be found needed and justified.

In general, I found both papers stimulating and informative. The suggestions regarding pooling, reserves of liquidity or goods, leasing, and information services deserve careful discussion and research, but I have neither the time nor preparation to offer constructive observations at this stage.

I would like to close with two miscellaneous observations. As we analyze response to uncertainty more completely, I suspect our analysis will become part of our general economic analysis rather than a separate field. Uncertainty pervades all activity, and it seems unlikely that we can satisfactorily separate decisions involving uncertainty from general decisionmaking except in our present very preliminary stages. The other miscellaneous point concerns Gray's final contrast between risk aversion and risk selection. As viewed by current theory, there is no need for this distinction. As observed by Barry and Fraser, a risk averter has diminishing marginal utility for income or wealth. This does not mean that he refuses to take risks, but that he chooses those which seem justified either because they offer sufficient opportunities for reward to outweigh the dangers of losses and/or they offer circumstances for gains and losses that are complementary to the decisionmaker's present prospects and thus tend to stabilize prospective wealth.

Discussion of Market Implications

Konrad Biedermann

The two papers presented at this session contain many points with which I can only agree, but also some thoughts with which one can take issue. In line with this, I would like first to share some thoughts that occurred to me while reading the two papers, and then add some observations made from my specific vantage point as financially-oriented researcher and investment analyst in a major agribusiness firm.

The Barry/Fraser paper focuses on increased price variability for the farmers' products as an indicator that financial risk in primary agricultural production has increased. Furthermore, the paper discusses risk management primarily in terms of minimizing price variability and stabilizing expected returns. I contend that price variability, in itself and without reference to the corresponding cost of production, does not prove that the probability of incurring a financial loss has increased. It merely establishes the fact that it will statistically be more difficult to obtain the highest price possible. As a case in point, aggregate net farm income during the years 1973 and 1974 has reached unprecedented heights, both in absolute dollars and in relation to assets employed. This was not the result of a very sudden increased sophistication on the part of farmers to deal with the greater product price variability.

The coefficients of variation for the annual mean prices shown in table 1 of the Barry/Fraser paper are meaningless in my opinion because they are influenced heavily by the length of period selected for analysis and by the underlying secular trend in price levels. The paper points to a growth of over 1200% in debt per farm between 1950 and 1975 and a payback period of nearly three years for this debt as indicators of decreasing ability of the farm sector to absorb financial risks. But comparing statistics from the U.S. Department of Agriculture's *Balance Sheet of the Farming Sector 1974* with comparable data for the Grain Processing Industry (SIC 2041) and the Agricultural Merchandising Sector, it becomes evident that these other sectors operate on a smaller gross profit margin and a much thinner cushion of financial reserves. This is what made it mandatory for them to devote major efforts to the task of risk management. Considering relative strength of net worth, it would take only a small fraction of the unhedged decline in the price of commodities to completely wipe out the net worth of a merchandising firm, compared to the decline necessary to completely dissipate the net worth of the farmer (see table 1).

Barry/Fraser also suggest that more frequent sequential marketing can reduce risk, which is correct if we assume that risk aversion is the ultimate goal. But sequential marketing does not optimize prices. It is an averaging procedure that only guarantees that something better than the lowest price will be obtained. Maybe this explains why pooling results achieved by the cooperatives, as well as by the Canadian and Australian Wheat Boards, have been mediocre at best.

Professor Gray's paper emphasizes institutional factors and the role of organized futures markets. I agree with his comments both in regard to the value of these institutions to our society and to the limitations still remaining. But in regard, for instance, to the lack of a sorghum futures contract, a broader definition by the Commodity Futures Trading Commission of bona fide hedging could do much to alleviate the present problem. Cross-hedging sorghum in corn futures gives essentially as much price protection as can be obtained hedging corn in corn futures.

Another problem mentioned is the need for added margin calls to hedgers during periods of adverse price movements. It would seem there should be an objective reappraisal of using commodity options to deal with this problem. (Obviously, I would be opposed to dealing in "naked options.") The hedger would in effect have already purchased with the option all additional margin potentially due if the market changes required it.

Konrad Biedermann is the director of planning at the Continental Grain Company, New York.

Table 1. Approximate Financial Structure of Agribusiness Sectors

	Farming Sector[a]	Manufacturers of Grain Mills Products[b]	Wholesalers of Grain[c]
Total sales (%)	100	100	100
Cost of sales (%)	74	89	90
Gross profit (%)	26	11	10
Net worth per $ of sale	$4.02	$0.17	$0.09

[a] USDA.

[c] Robert Morris Associates, p. 119, SIC 5153.

Professor Gray's paper also refers to the Chicago delivery problem and a need for multiple delivery points. It may be just a matter of semantics, but it seems to me we have and want to maintain a futures market with a single pricing point but with alternative delivery points. We now have this situation for Chicago Board of Trade wheat, corn, oats, soybean oil, and soybean meal futures.

Use of futures markets has played a key role in the ability of the trade to handle price risk. But there are other agricultural market risks that also have increased greatly during the last few years. While these risks have been enlarged by the greater price variability of recent periods, they often cannot be shifted to speculators through such mechanism as a futures market. Risk management in these areas often requires an adjustment of internal procedures and tighter management controls. I shall try to list just a few of them.

The grain trade has always prided itself on the fact that contracts to buy or sell were honored by all sides, with defaults being a very rare occasion, even though initially they were made verbally and only later confirmed in writing. On the buying side, however, our industry did experience a very pronounced increase in defaults by farmers who had forward contracted for the sale of their crop during the spring and summer of 1972 and then did not deliver at harvest time. This, of course, was a period of rapidly rising prices, and for those firms who had hedged these volumes in the futures market in anticipation of applying them to already incurred sales, this led to significant losses. As a result of this experience, our industry has become more selective when screening the capability and willingness of prospective forward contractors to actually perform, regardless of the magnitude of price movements between contract time and harvest. Ultimately, performance could be guaranteed by some kind of escrow payment, which, of course, would tend to increase marketing costs.

The incidence of contract defaults on the buying side in our business has declined again, and in retrospect these losses have been of much lesser magnitude than the ones caused by subsequent contract defaults on the part of some foreign governments. Probably the largest case occurred when the Turkish government in March 1975 refused to open letters of credit for the delivery of purchases they had made during the latter part of 1974, when price levels had been some 25% higher. The potential loss on that contract alone on a fully hedged basis had been reported in the press as over $30 million. Even though international courts in London have, in the meantime, upheld the validity of the contract, it will be nearly impossible for a private firm to collect from an unwilling and uncooperative foreign government. Again, these experiences have led to a distinct tightening of contract provisions, especially the insistence of immediate opening of letters of credit on the part of the foreign buyer. This, of course, adds to the cost of the commodity and the ultimate price the recipient is, in effect, paying.

The higher price levels and greater variability in prices also make it difficult for processors and marketing firms, as well as for the farmer, to closely estimate their future credit needs and cash flows. As a result, all of these firms must arrange beforehand for larger credit lines than they may actually need. To the extent that a commitment fee is required for standby credit lines, this increases the cost of performing the marketing function.

Still another kind of new risk has been created by the need to maintain greater levels of fixed investment at a time when the firms themselves have become increasingly subject to disruptive outside influences. These outside influences make it extremely difficult to fully and effectively utilize the larger investment. For instance, as a result of the shortage of rail transportation equipment, over the last ten to fifteen years the grain merchandising and processing industries have come to purchase or lease over 50,000 covered hopper cars. Mileage earnings from the railroads cover only a part of this new long-term financial commitment. However, greater availability of on-farm storage (which is welcomed as a leveling influence in marketing volumes throughout the

year) combined with great price variability make it possible for farmers to completely hold their grain off the market for certain periods. This makes level and continuous use of this expensive transportation equipment impossible to achieve for our industry.

As another example, export elevators have been requiring additional investment for air pollution control and for upgrading of handling speeds to load large bulk-carrier ships faster. But there is less ability on the part of the industry to plan for continuous and effective use of these expensive tools because such developments as government embargoes on export shipments or boycotts of longshoremen of foreign flag vessels can close down these facilities unexpectedly and for indefinite periods. All of these risks, of course, add to the cost of doing business.

But it would be wrong to conclude from all this that the increased financial risk has worked to the distinct disadvantage of the industries involved or that a socialist or centrally planned economy would be much better equipped to cope with it. Farm income has never been higher than in the last three years, and, to date, the processing and marketing firms have been able to generate the new capital required to cope with the increased volume and higher price levels. Furthermore, the American consumer still is getting his food at a substantially lesser percentage of his disposable income than people in any other country around the world. At the same time, agricultural exports from the United States made a very crucial positive contribution to our balance of foreign trade.

Risk, when properly managed, holds opportunities for gains, as well as losses. Based on the record of all of the participating industries, risk management (availability of tools, as well as extent of use) has been successful to date. While there will always be room for improvement, it is to the credit of our economic system that it permits industries to flourish under these conditions.

Discussion of Policy Implications

Richard L. Sandor

In this discussion, my assignment is to evaluate briefly the policy recommendations made in the papers by Barry and Fraser (hereafter B-F) and Gray, as well as developing the policy implications that are not specifically made by the authors. Although both papers contain interesting questions related to policy, there is a paucity of specific recommendations. Therefore, subsequent parts of this discussion will be devoted to discussing the questions as well as considering policy recommendations and implications.

The B-F paper explicitly recognizes the increased market risks that confront producers and qualitatively examines risk responses according to the size distribution of primary agricultural producers. The discussion includes both financial and market responses to risk. Market responses that include inventory management and forward contracts appear to be less available to the small producer. There have been market reactions to the need and demand of the small producers such as the creation of cooperatives. These institutions provide an alternative to the small producer for using arrangements and institutions that may not be available to the firm on an individual basis. Policymakers should be aware of the social value of these institutions in formulating policies that may affect their operations. Although cooperatives provide some solution to the problems of the small producer, they may be insufficient. The authors quite properly emphasize the need for greater management and information among producers in the current market environment. The implicit and explicit references to increased levels of education is particularly worth noting. Public universities have traditionally provided support for producers through the development of degree programs oriented toward producers as well as extension activities. However, the emphasis on production to the exclusion of marketing and finance that was proper in an environment characterized by price support programs is currently inappropriate. It appears reasonable to suggest that this inadequacy of the system be confronted directly and that policymakers define specific programs to meet the current needs of producers. This is particularly important to the small producer with management limitations.

B-F present the argument that institutional arrangements such as the size of futures contracts provide a constraint to the small producer, i.e., indivisibility imposes disadvantages to the small producer. In this regard their paper should contain reference to the MidAmerican Commodity Exchange, which has contracts that are smaller than those on the Chicago Board of Trade and other exchanges, e.g., a corn contract of 1,000 bushels versus 5,000 bushels. Consequently, according to their analysis a farm unit of only 40 acres and not 200 is necessary for a single contract. Although there has been some concern about the proliferation of futures contracts, the Commodity Futures Trading Commission should be particularly aware of the potential value of the multiple trading of contracts of the same commodity but of different size.

Another point worth noting is the recommendation of the authors that there be greater ties between rural areas and major money market centers. This was particularly important in 1973 when significant margin requirements were necessary to finance even modest short hedges. More efficient ties in the capital markets would tend to diminish the possibility of a regional credit crunch. Furthermore, it would seem desirable for bankers in money market centers throughout the country to understand organized futures markets to improve the flow of capital in this sector. There are probably a wide variety of reasons that cause futures markets to exhibit an intertemporal price structure with more than full carrying charges, but inadequate knowledge of these institutions may be a contributing factor. The intent of Congress with respect to the

Richard L. Sandor is Vice-President at ContiCommodity Services, Inc., Chicago, and a visiting professor of finance of the Graduate School of Management, Northwestern University, Evanston.

educational function of the CFTC is particularly worth noting in this context.

High margin requirements, low liquidity, and reduced financial leverage described by B-F mitigate against the use of organized futures markets. There appears to be a policy that could be implemented by regulators and legislators that might be implemented to facilitate risk transfer. As B-F state, "Arrow further characterizes market perfection in transferring risks as the emergence of market institutions for freely insuring against an economically relevant event with premiums determined by supply and demand for the contingency claims." It appears that the preceding is a rational argument for legally permitting the trading of options on futures markets. A market test of this concept might be used to determine if options could be used as a means for insuring against certain economically relevant events. If it appeared feasible, then one can imagine the possibility of trading more complicated contingent contracts on organized exchanges, e.g., an option on a futures contract that is exercisable under certain weather conditions. Of course, liquidity limitations would probably limit any proliferation of contingent contracts.

The Gray paper raises many interesting policy questions rather than making specific recommendations. Subsequent comments will simply be devoted to briefly commenting on them rather than developing lengthy implications for policy based on hypothetical answers. Our organization will follow his outline.

In contrast to the B-F paper, Gray emphasizes certain institutional factors accompanying the change from governmental mechanisms to the marketplace for risk transfer. Gray quite accurately describes how organized futures markets absorbed the increased risk. The difficulties associated with the inability of the markets to completely facilitate the transfer of risk among nonprimary producers may also be explained in terms of inadequacies in human capital. The analog is the lack of exposure of corporate management to futures markets in degree and extension programs in schools of business administration and management. The educational function of the CFTC as well as the universities should both be mentioned at this point.

It seems appropriate within this discussion paper to digress briefly on a particular reference of Gray's regarding the possibility that the lack of hedging may require some regulatory oversight. It appears worthwhile recommending that extreme caution be pursued in implementing any recommendation regarding limitations on what risks, if any, decisionmakers should be permitted to assume in their own operations. Of course the latter must be considered in the context of firms honoring legal contracts.

An extremely important aspect of the Gray paper is the statement regarding "official neglect of the sanctity of contracts." The impact on holders of futures contracts was only the first of many effects of the grain export embargo. The introduction of greater uncertainty into the system by such events create greater costs for society. The effectiveness of market responses to risk, such as hedging, is clearly reduced when the markets become subject to certain types of political decisions. A curious side effect of the embargo may have been the achievement of the exact opposite effect than was intended. Latent demand by foreign nationals for agricultural commodities may have been released as a result of greater uncertainty regarding the United States as a source of supply.

Some of the more important policy implications in the Gray paper emerge from the discussion of the CFTC. The intent of Congress was that increased regulation was necessary to preserve and promote the integrity of the free market. As a brief aside, it is certainly a curiosity that Congress would retain a law banning futures trading in onions while reaffirming its belief in this mechanism. It will also be interesting to observe if a regulatory agency whose raison d'etre is the promotion of competitive markets will seek market solutions in the course of performing its regulatory function. A related but different question is concerned with the eventual ratio and/or composition of staff economists to attorneys in an agency in which a significant portion the responsibility resides in determining the economic justification for contract markets. In both of these areas the commission has significant opportunities for innovation within the regulatory framework.

The discussion of the Chicago Board Options Exchange and the Government National Mortgage Association mortgage interest-rate futures contract leads one to inquire into the proper relationship between regulatory bodies. Regulatory agencies in protecting their

jurisdiction may impose significant costs on industry and the taxpayer. The need to clearly define the authority of regulators may not only require a resolution in the courts but a greater degree of coordination. It seems reasonable to wonder if innovation is aided or hindered in a system that requires significant expenditures both by the private and public sector to determine who should regulate an activity rather than what the objectives of regulation should be. A significant portion of our research and development for interest-rate futures was devoted to developing a contract within an uncertain regulatory environment. The fact that the Securities and Exchange Commission still claims jurisdiction not only imposes additional costs but may even threaten the success of the market by imposing uncertainty on principals and agents operating on the exchange.

The implication that certain problems, such as the Chicago delivery problem, may be resolved under regulation must be viewed cautiously since the proposal accepted by the Commission was a modification of the one originally submitted to the Commodity Exchange Authority. A question regarding the proliferation of new contracts on several exchanges still has to be determined. It is essential that competition among exchanges with regard to its impact on promoting inventive activity be understood by the CFTC.

Gray raises some interesting questions in the section on "Some Remaining Problems." Is the market test of survival sufficient economic justification for a futures market? What is the optimum level of hedging? These and other unanswered questions may also have significant policy implications.

One final point regarding organized futures markets and cartels emerges throughout the paper. If organized futures markets have provided the effective risk transfer mechanism described by Gray, the policymakers should promote the uses of this mechanism wherever possible rather than support international agreements. Further but limited evidence of the role of organized futures markets in promoting price stability and providing a market test of price expectations suggests an even greater reliance on this mechanism.

The purpose of this discussion has been to emphasize some of the more important questions raised in the B-F and Gray papers as well as examining policy implications. Answers to the numerous questions raised by the authors should provide significant value to policymakers in formulating the legal and regulatory environment of futures markets.

Notes

Implications of Short-Run Rising Average Productivity in Cattle Feeding

Ewen M. Wilson

The recent period of high grain and low cattle prices has inspired renewed questions about economic efficiencies in cattle feeding. Unfortunately, despite solid theoretical foundations and some empirical investigations (Heady and Dillon, O.E.C.D., Heady et ai.), agricultural economists appear unable to reach a consensus. The initial inclination arising from usual production and marginal substitution criteria is to prescribe a move down the production function (less feed for less gain) and/or dilution of high energy rations with lower energy and lower cost ingredients (a downward shift of the production function). This note proposes to demonstrate that the first prescription is inappropriate and that the second is questionable and inappropriate within narrow delimitations specified here.

In particular, there is evidence that cattle feed-gain response functions do not fall in stage II of production. Zulberti, Reid, and Casler have inferred from animal nutrition work (Blaxter, Dodsworth) that cattle feeding is constrained by appetite limitations to the rising average physical product portion of the production function (stage I of production). Their use of British Agricultural Research Council nutritional information to test the hypothesis has led them to conclude that "for feeds of any given concentration the producer has only to decide between feeding *ad libitum* or not feeding at all" (Zulberti, Reid, and Casler, p. 10). Brokken has provided an excellent review of the net energy system suggested by Lofgreen and Garrett and subsequently adopted as beef-cattle feeding recommendations by the National Research Council of the National Academy of Sciences (hereafter NRC). Brokken et al. have recently employed this system in a fairly broad framework to look at the feed-energy concentration issue, an issue that they conclude remains unresolved. Nevertheless, their results tend to lean in the direction of higher rather than lower energy cattle feeds as do the earlier results of Heady et al.

The specific objectives of this note are to use the NRC system to test the stage I hypothesis and to analyze relative economic efficiencies of two energy-specific rations. The focus is upon feed-gain relationships and cost curves for a steer of given weight on a daily basis. No attempt is made to address the more complex, longer term questions of overall economic efficiency in cattle-feeding operations. The latter questions are, without doubt, important. They are also difficult to answer. In the search for less ambiguous answers, this note confines itself to a narrower framework. Nevertheless, the daily feed-gain relationships portrayed here are, in effect, underlying components of the feed-gain trajectory over time. In this sense, they are directly relevant to longer term feedlot profit analyses. (See Brokken et al.)

Ewen Wilson is an assistant professor of agricultural economics at Virginia Polytechnic Institute and State University.

Appreciation is expressed to J. Havlicek, R. B. Jensen, and other colleagues in the Department of Agricultural Economics at Virginia Polytechnic Institute and State University, and also to R. B. Brokken and an anonymous reviewer for helpful comments.

Conceptual Framework

The NRC system expresses energy needs of beef animals of given liveweight in terms of daily net energy requirements for maintenance plus daily net energy requirements to sustain a specified rate of gain. Feedstuff energy concentration is measured as net energy available for maintenance and net energy available for gain (both expressed on the basis of a unit dry matter feed).

Dividing cattle energy requirements by the appropriate feed energy concentration values yields

$$(1)\quad f = [A + Bg/2.2 + C\,(g/2.2)^2]\,(W/2.2)^{0.75},$$

where $A = A'/\epsilon_m$, $B = B'/\epsilon_g$, $C = C'/\epsilon_g$, f = daily feed requirements (pounds dry matter), g = liveweight gain per day (pounds), W = liveweight of the animal (pounds), ϵ_m = net energy concentration of the feed for maintenance (megacalories per pound dry matter), ϵ_g = net energy concentration of the feed for gain (megacalories per pound dry matter), and where $A' = 0.077$, $B' = 0.05272$, and $C' = 0.00684$.[1] The alternative form of equation (1) is

$$(2)\quad g = 2.2\,\{-\gamma + [\gamma^2 + (f/(W/2.2)^{0.75} - A)/C]^{0.5}\},$$

where $\gamma = B/2C$.

Thus, for a suitable cattle-feeding ration of known analysis (energy concentration), the total daily gain function, for an animal of specified

[1] Parameter values (A', B', C') are taken from NRC and pertain to steers (NRC, p. 3). A factor of 2.2 has been used to convert kilogram units to pounds. For heifers, $B' = 0.05603$ and $C' = 0.01265$. The present analysis is confined to steers.

liveweight, may be determined as a function of daily feed, while average and marginal daily gain functions are g/f and $\partial g/\partial f$, respectively. In order to cast these production relationships in an economic framework, it is only necessary to know the ration price when total daily feed cost may be expressed as

$$F = Pf/k, \tag{3}$$

where F = total daily feed cost ($ per day), P = cost of the ration ($ per pound "as fed"), and k = fraction dry matter of the feed. Average and marginal daily feed costs with respect to gain are F/g and $\partial F/\partial g$, respectively. These production and cost relationships have been computed and are plotted in figures 1 and 2 for two rations specified in table 1. Based on NRC formulas, ration 1 contains approximately 70% total digestible nutrients (TDN), while ration 2 contains slightly less than 76% TDN (National Academy of Sciences, p. 19). Ration costs are based on $2.60 per bushel corn, $50 per ton hay, and $170 per ton supplement.

Appetite Constraint

In theory, if cattle could be induced to consume larger quantities of feedstuffs of higher energy content, they would effectively move down the average feed-cost curve and up the average physical product curve. In practice, physical barriers to feed intake and liveweight gain do exist. A crude rule of thumb commonly encountered in the cattle industry is that cattle consume daily between 2% and 3% dry matter equivalent of their body weight. For instance, the *Feed Industry Red Book* uses a 16- to 17-pound dry matter intake range (2.75% body weight average) for 600-pound steers rising to a 23-

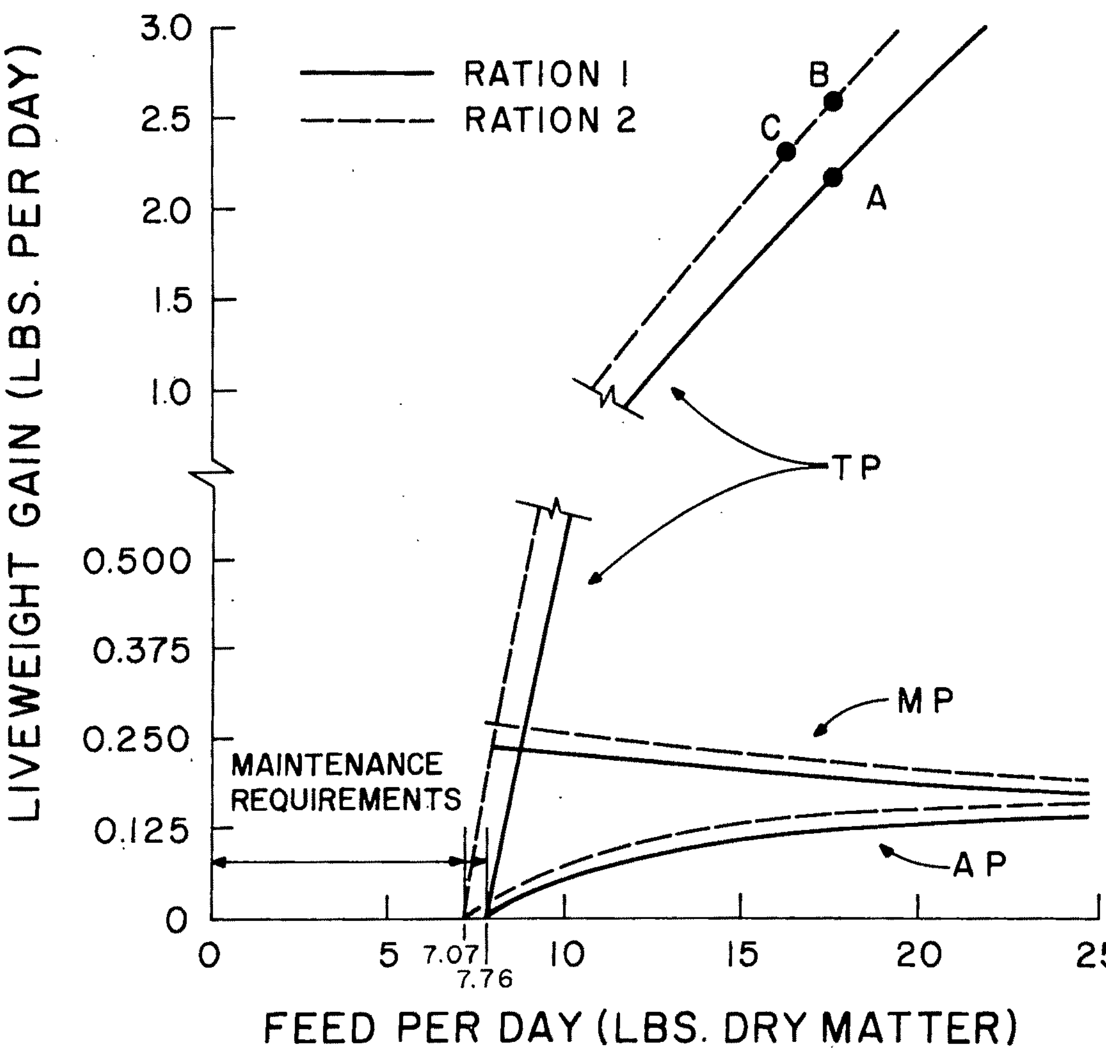

Figure 1. Total (TP), average (AP), and marginal (MP) production relationships for 700-pound steer on alternative rations

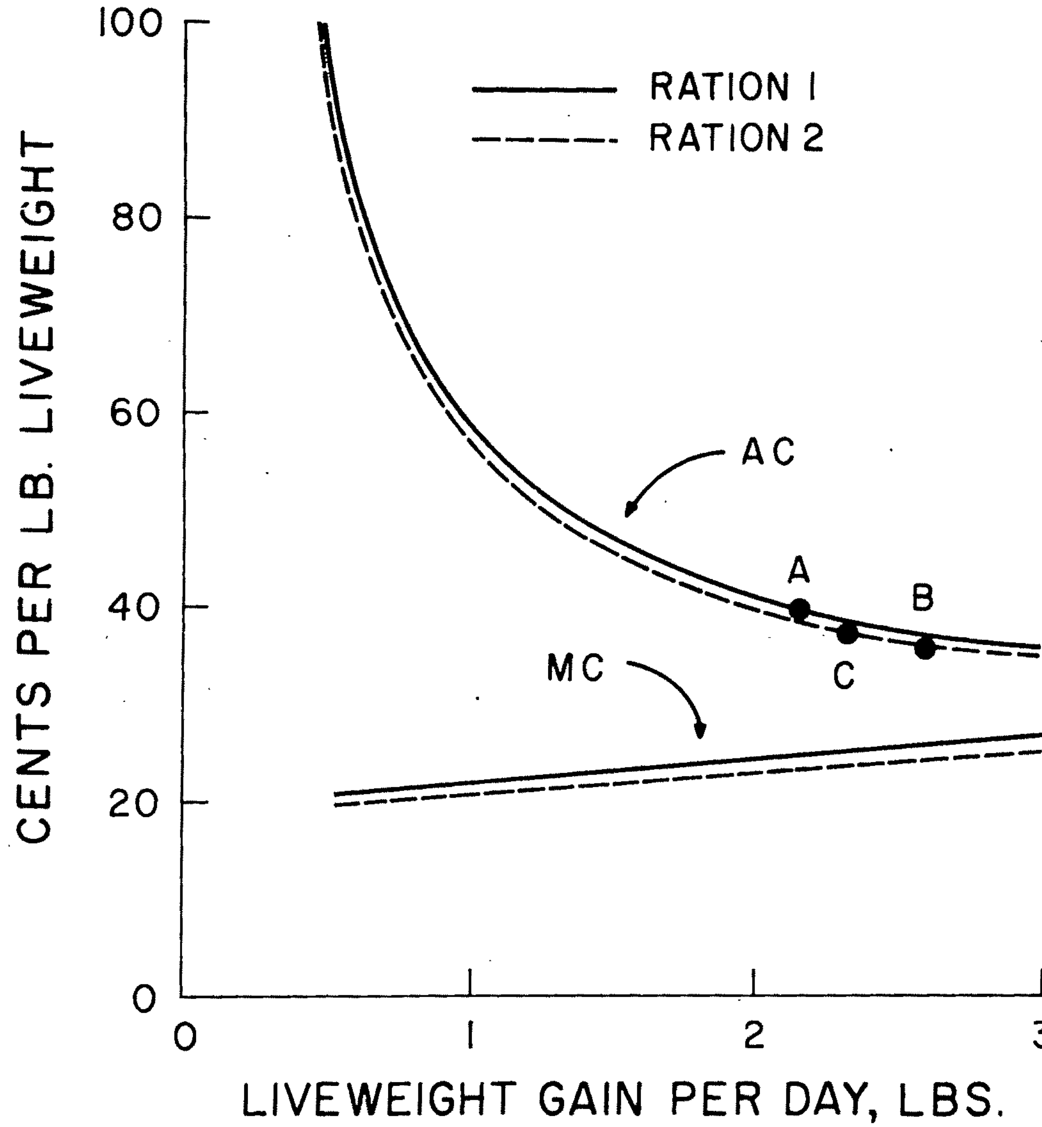

Figure 2. Average (AC) and marginal (MC) feed cost curves for 700-pound steer on alternative rations

to 25-pound range for 1000-pound animals (2.4% average).

If it were assumed that regardless of feed-energy concentration, 700-pound steers consumed 17.58 pounds of dry matter per day (just over 2.5% body-weight equivalent), then the predicted gain rate for ration 1 would be 2.2 pounds per day (point A in figure 1) versus 2.6 pounds for ration 2 (point B). On this basis one might be tempted to conclude that the higher energy ration is more efficient (higher average physical product) and less costly per pound gain (A versus B in figure 2) than the lower energy ration. In fact, such a conclusion would be premature since it ignores the effect of different feedstuff energy concentrations on voluntary appetite. In practice, daily dry matter intake of low energy (high roughage) rations is limited by rumen capacity. However, as energy concentration of the ration increases, there comes a point where rumen capacity ceases to be limiting but where chemostatic and thermostatic factors take over to inhibit daily dry matter intake (daily physiological energy requirements are satisfied within rumen capacity limitations). The latter phenomenon is widely accepted in the literature (Montgomery and Baumgardt, Dinius and Baumgardt, Elliott and Reed, Brokken and Dinius), although the exact causal mechanism is not fully understood (Elliott and Reed).[2]

[2] The feed energy level at which rumen capacity ceases to be the limiting factor was estimated by Dinius and Baumgardt to be 2.47 Mcals DE (digestible energy) per kg. dry matter for sheep and was reassessed by Brokken and Dinius at 2.82 Mcals per kg. dry matter for cattle. Using relationships described by the NRC,

Table 1. Composition and Analyses of Two Cattle-Fattening Rations [a]

	Ration 1	Ration 2
Ingredients (% "as fed")		
Corn grain	58	75
Orchardgrass hay	32	15
Protein supplement [b]	10	10
Complete ration	100	100
ϵ_m (Mcals/lb dry matter)	0.7473	0.8209
ϵ_g (Mcals/lb dry matter)	0.4490	0.5132
Crude protein (%)	12.40	12.46
Dry matter fraction	0.8888	0.8899
Cost (¢/lb "as fed")	4.34	4.71

[a] Based on NRC analysis.
[b] Proprietary brand protein-mineral supplement analyzing 90% dry matter. 50% crude protein and 0.6182 and 0.3455 Mcals net energy per lb. dry matter for maintenance and gain, respectively.

Based on regression of experimental data, Brokken et al. have provided a quantitative evaluation of the relationship, which can be written as

$$(4)\quad f_v = (0.094138 + 0.0625/\epsilon_g)\ (W/2.2)^{0.75},$$

where notation is unchanged from before except that f_v denotes voluntary daily dry matter feed intake in pounds. Evaluated for 700-pound steers, equation (4) yields a daily dry matter voluntary intake of 17.58 pounds for ration 1 and 16.27 pounds for ration 2 (points A versus C in figures 1 and 2).[3] Use of these points to compare the two rations indicates that despite the higher unit cost of the higher energy ration, the latter still has an advantage over the lower energy ration in terms of average feed cost (37.4¢ versus 39.7¢) and average physical product (0.142 versus 0.123). In terms of feed conversion efficiency (pounds feed per pound gain), which is in effect the inverse of average physical product, the comparisons are 7.06 versus 8.12 on a dry matter basis, or 7.94 versus 9.14 on an "as fed" basis (corrected for dry matter fraction).

Effect of Varying Prices

The preceding section supports the hypothesis that cattle-feeding production relationships are constrained by appetite limitations to stage I of production and indicates that, at the stated feed prices, the higher energy ration is preferred from an economic efficiency viewpoint. The next logical step is to analyze the effect of variations in price of the energy-rich ration ingredient (corn) upon relative economic efficiencies of the two rations. The object is to determine whether the increasing cost of the higher energy ration relative to the lower energy ration is sufficient to offset the physical efficiency advantage of the higher energy ration.

The feedlot operator is interested in returns over feed costs to other feedlot costs (labor, veterinary, medicine, interest, transport, and marketing fees) and to fixed overheads (depreciation on facilities, taxes, and the like). Assuming that he perceives an expected market price for his cattle, then it is appropriate to compare the daily margin between this expected price and daily feed costs as a measure of relative economic efficiency of the two rations. If the expected cattle price is denoted by R dollars per pound, then daily margin over feed costs, π dollars per head, may be written in terms of earlier notation as[4]

$$(5)\qquad \pi = Rg - F.$$

Total daily feed margin is shown in table 2 for a range of cattle prices ($35, $40, and $45 per 100 pounds) and corn prices ($2.20 up to $3.80 per bushel), where equation (4) has been used to establish appetite level and g and F have been calculated from equations (2) and (3), respectively. Other feed ingredient prices are unchanged from before ($50 per ton orchardgrass hay, $170 per ton protein supplement).

For the range of cattle and corn prices employed in table 2, the higher energy ration has the advantage except when corn prices are $3.80 per bushel and cattle prices $35 per 100 pounds, in which case the lower energy ration has a slightly lower negative margin. This price combination is for all practical purposes untenable (it represents a steer-corn ratio of 9.2).[5]

From table 2 the effect of a 1¢ per bushel rise in corn prices on daily feed margin is −0.245¢ for the higher energy and −0.205¢ for the lower energy ration. The effect of a $1 per 100-pound rise in cattle price on daily feed margin is 2.32¢ and 2.16¢ for the respective rations. For the period 1950 through 1972, the standard deviation for corn prices was 18.35¢ per bushel and for cattle prices $4.16 per 100 pounds.[6] These standard deviations can be

these values convert to 0.2341 and 0.3594 Mcals net energy for gain per lb. dry matter, respectively (NRC, p. 19).

[3] Daily dry matter intake relationships are commonly expressed by animal scientists on a per unit metabolic weight basis. That is, in our notation, $f_v/(W/2.2)^{0.75}$. (See Dinius and Baumgardt.) When equation (4) is substituted into equation (2), daily liveweight gain becomes a function of energy but independent of weight. The implications are that cattle on a specified energy concentration feed grow at a constant rate of gain but diminishing feed efficiency (lbs. feed per lb. gain). Brokken et al. indicate that the constant rate of gain assumption causes very little aggregation error over the entire feeding period. In any event, these implications are of secondary importance here, since equation (4) is being used purely to establish feasible appetite reference points for comparison of the two rations.

[4] The emphasis here is upon profit per unit time rather than profit per unit weight gain as in Brokken et al. Equation (5) is conceptually analogous to their partial derivative of total revenue with respect to time minus their partial derivative of total cost with respect to time.

[5] For the period 1950–72 the mean steer-corn ratio measured as annual average choice steer prices at Omaha ($ per 100 lbs.) divided by annual average corn prices recieved by farmers ($ per bushel) was 22 with a coefficient of variation of 0.18 (USDA 1973, 1972).

[6] Based on the price series cited in note 6, the mean steer price for the period 1950–72 was $26.63 per 100 lbs. (with standard

Table 2. Feed Costs and Daily Margin over Feed Costs for a Range of Cattle and Corn Prices, 700-Pound Steers on Alternative Rations

Corn Price ($/bu.)[a]	Ration Cost (¢/lb.)[a]	Marginal Cost of Lb. Gain (¢)	Average Cost per Lb. Gain (¢)	Daily Margin (¢/day) over Feed Costs When Cattle Price ($/100 lbs.) Is 35	40	45
Ration 2						
2.20	4.2	21.0	33.1	4.3	15.9	27.4
2.60	4.7	23.7	37.4	−5.5	6.1	17.6
3.00	5.2	26.4	41.6	−15.2	−3.7	7.8
3.40	5.8	29.0	45.9	−25.0	−13.5	−2.0

Ration 1						
2.20	3.9	22.3	35.9	−1.9	8.9	19.7
2.60	4.3	24.7	39.7	−10.1	0.7	11.5
3.00	4.8	27.0	43.5	−18.3	−7.5	3.3
3.40	5.2	29.4	47.2	−26.5	−15.7	−4.9
3.80	5.6	31.7	51.0	−34.7	−23.9	−13.1

[a] On "as fed" basis.

used as crude weighting factors to estimate the relative effects of corn and cattle prices on daily feed margin. Thus, the weighted effects on daily feed margin of increases of 1 ¢ per bushel corn and $1 per 100-pound cattle are −4.50 and 9.65, respectively, for the higher energy versus −3.76 and 8.99 for the lower energy ration. Evidently cattle-price changes have potential for greater effect on daily feed margins (and therefore feedlot profit) than do corn-price changes. The implication is that as cattle and corn prices trend upwards over time daily feed margins will improve.[7] (It is also likely that other feedlot costs will inflate over time, offsetting the benefit of increased daily feed margin.)

Conclusions

The widely accepted NRC system has been used to demonstrate that cattle feeding is constrained by voluntary appetite to stage I of production, where the production function is expressed as the daily feed-gain relationship for rations of specified energy density. More specifically, feed-gain relationships appear to be confined, for practical purposes, to the rising average product portion and the diminishing marginal-product portion of the production function (beyond the point of inflexion of the total product curve). The implication is that in a positive profit situation cattle ought to be fed for maximum daily gain, since this is equivalent to the lowest attainable point on the average cost curve.

When two rations of different energy concentrations were compared, the higher energy ration was preferred on grounds of physical and economic efficiency over a relevant range of corn and cattle prices. Although based on a 700-pound steer, these results appear to hold for a range of feasible animal weights (not reported here). Results would be strengthened by comparison of a wider selection of rations and ingredients.[8] Nevertheless, they do indicate, in the short run at least, that maximum profit (minimum loss) is attained with higher rather than lower energy rations (presumably with ingredients selected on basis of least cost).[9] In the case in which cattle prices fall below average feed costs per unit gain, the decision reverts to one of "full-feed versus no-feed" since daily appetite limitations preclude movement down the average feed-cost function.

deviation 4.16) and mean corn price 123.48 ¢ per bushel (standard deviation 18.35).

[7] This may be confirmed by comparing daily feed margins for cattle at $45 per 100 lbs. and corn at $3 per bu. (15.0 steer-corn ratio) and cattle at $40 per 100 lbs. and corn at $2.60 per bu. (15.4 steer-corn ratio).

[8] Below a certain energy concentration level, equation (4) would not be appropriate for determining voluntary appetite due to rumen fill limitations (see note 3).

[9] The emphasis may change in a longer run feedlot profit analysis in which additional factors such as time costs and changing grade-price relationships are taken into account, or where alternative systems in a multienterprise framework are compared. Brokken et al. suggest that roughage (lower energy) fares better when profit per head rather than profit per unit time is the optimizing criterion.

An Economic Analysis of the U.S. Poultry Sector

Dale Heien

During 1973 consumers experienced the sharpest food-price inflation in the United States since World War II. Food prices rose an estimated 16%. Contributing substantially to the increase in food prices was poultry, which increased 40%. Price increases for poultry in 1974, while not as large as in 1973, were again substantial. Beef, pork, and poultry constitute the major portion of U.S. protein intake with consumption at 110.8, 62.2, and 50.5 pounds per capita, respectively, in 1973. Poultry consumption comprises turkey (8.9 pounds per capita in 1973), broiler chickens (37.6 pounds per capita), and "other" chickens (4 pounds per capita). The 1973 total of 50.5 pounds is up substantially from the 24.2 pounds in 1950. One reason for this increased consumption is the long-run decline in poultry prices from 1950 to 1972 mainly as a result of low corn and soybean prices, and the increased demand for "fast food" outlets. Poultry occupies a relative importance of 4.1% in the food-at-home portion of the consumer price index for 1973 compared with 12.4% for beef and veal and 7.3% for pork. Approximately 3.5% of farm income comes from poultry operations, with Georgia, Arkansas, Alabama, and North Carolina ranking as the largest producers. The industry is characterized by a high degree of vertical integration, so much so in fact that it is difficult to identify the farm price of poultry. Also, the industry is highly concentrated (for the agricultural sector) with 47% of broiler production being accounted for by the top twenty firms in 1968 (USDA).

This note briefly describes an econometric model of the U.S. poultry economy. The model is then used to measure the impact on the poultry economy (in both the short and long run) of changes in various key influencing factors, such as aggregate income and price level, the price of close substitutes (beef and pork), and cost variables including corn and soybean meal prices. Next, the poultry price inflation of 1973 is analyzed by decomposing the overall price changes into the sum of the various influencing factors.

Dale Heien is a consultant in Washington, D.C.

The model described was prepared under contract with the Economic Research Service, U.S. Department of Agriculture. The author would like to acknowledge the help and cooperation of the staff of ERS, especially Richard Haidacher, Robert Hoffman, Rodney Kite, and James Matthews.

Description of the Model

The model of the poultry sector presented here involves seventeen endogenous variables and ten exogenous variables. The poultry economy is composed of three products, turkeys, broilers (young chickens), and other chickens (hens, surplus cockerels, and fowl from egg-producing flocks). Each product sector contains a retail demand equation, a farm-level demand equation, a production relation, and a stock equation. Total supply for each product is specified as a function of the farm (or wholesale) price for that particular product, the feed-cost variable (a weighted average of corn and soybean meal prices), the wage rate for that industry, an industry-capacity measure (a proxy for capital stock), and a time trend for technical change. The price and cost variables are entered as ratios in the supply relations in order to preserve homogeneity. This is in keeping with the theoretical specification of supply curves in terms of relative prices (Walters). Frequently, agricultural supply response relations are fitted without this restriction. The main justification for not using ratios is that data do not exist on all input costs. In the absence of complete input cost data, both approaches produce biased estimates. However, the ratio form will be tractable in terms of the bias. Also, the ratio form increases the degrees of freedom.

Total consumption for each product is then determined by subtracting exports, military purchases, U.S. Department of Agriculture donations (all exogenous), and ending stocks from total supply. Relations for ending stocks were obtained by specifying average stocks held during the year as a function of total output and a time trend to account for improved inventory procedures over time. Since the model is based on annual data, there is very little fluctuation in stock levels from year to year. This is understandable since short-run stock fluctuations average out over the course of a year as production and orders are adjusted to demand at the retail level. Given these stock equations, the quantity side of the model is complete.

Retail prices for each product are estimated as price-dependent demand relations. The demand for each product is specified as a function of the normalized price of that product and the normalized price of competing products (beef, pork, and all

other goods). Normalized prices (prices divided by per capita money income) were chosen for several reasons. First, they are theoretically more satisfying in terms of the mixed demand systems implied by price-dependent relations (Heien, Samuelson). Second, they conserve on degrees of freedom and hence alleviate somewhat the multicollinearity problem. Third, as an empirical matter, they tend to outperform relative-price real-income price-dependent demand systems in a predictive sense. Farm-level prices were also estimated in a price-dependent manner. These relations specify the ratio of the farm price to the retail price as a function of the output of each product and the ratio of the retail price to input costs such as wage rates and feed prices. Such relations may be termed price-dependent derived demand curves for factor inputs (Heien).

Model Estimates and Evaluation

The model was estimated by ordinary least squares (OLS) using annual data from 1950 to 1969. The main reason for not using a simultaneous technique is the near recursive nature of the model. Also, although OLS estimators are biased in a simultaneous equation context, so are all other estimators. Given the small sample and the sensitivity of simultaneous techniques to specification error, which is always present, full-information techniques are questionable.[1] The numbers in parentheses below the coefficients are the t-ratios. The numbers below the t-ratios are the elasticities at the means.

$\bar{R}^2 = 0.628$ S.E.E. $= 0.386\text{E}+08$ D.W. $= 1.22$.

$$TSBC = TPBC + ESBC_{-1}.$$
$$TSCEB = TPCEB + ESCEB_{-1}.$$
$$TST = TPT + EST_{-1}.$$
$$TCCBC = TSBC - ESBC - XBC.$$
$$TCCT = TST - EST - XT.$$

The variables used above are defined as follows, where the symbol + designates exogenous variables. $CAPBC^+$ = capacity in the broiler industry, computed using peak-to-peak method; $ESBC$ = ending stocks of broiler chickens; $ESCEB$ = ending stocks of chicken except broilers; EST = ending stocks of turkey; FCT = feed cost variable for turkey production, $0.75(PC/1.12) + 0.25(PSM/2.8)$; FCV = feed cost variable for broilers and chicken except broilers, $0.65(PC/1.12) + 0.35(PSM/2.8)$; FPT = farm price of turkey; PAO^+ = price index of all nondurables and services, except beef, pork, poultry, and fish; PC^+ = price of corn; $PCENDS^+$ = personal consumption expenditures on nondurables and services; POP^+ = U.S. population; PSM^+ = price of soybean meal; RPB^+ = retail price index for beef; RPC = retail price index for frying chicken; RPF^+ = retail price index for fish; RPP^+ = retail price index for pork; RPT = retail price of turkey; t = time trend (1950 = 1.0, 1951 = 2.0, etc.); $TCCBC$ = total civilian consumption of broiler chicken; $TCCCEB$ = total civilian consumption of chicken except broiler; $TCCT$ = total civilian consumption of turkey; $TPBC$ = total production of broiler chicken; $TPCEB$ = total production of chicken expect broilers; TPT = total production of turkey; $TSBC$ = total supply of broiler chicken; $TSCEB$ = total supply of chicken except broiler; $TSFB^+$ = total supply of fed beef; TST = total supply of turkey; $WPBC$ = wholesale price of broiler chicken; $WPCEB$ = wholesale price of chicken except broiler; $WRPP^+$ = wage rate in the poultry processing industry; XBC^+ = military purchase of broiler chicken plus exports of broiler chicken plus USDA contributions; XT^+ = military purchase of turkey plus exports of turkey plus USDA contributions; $ZAO = PAO/(PCENDS/POP)$; $ZBEEF = RPB/(PCENDS/POP)$; $ZC = RPC/(PCENDS/POP)$; $ZFISH = RPF/(PCENDS/POP)$; $ZPORK = RPP/(PCENDS/POP)$; $ZTURK = RPT/(PCENDS/POP)$; and $ZWPCEB = WPCEB/(PCENDS/POP)$.

In order to provide some form of evaluation for the model, a prediction interval test outside the sample period was performed. The results are given in table 1.

Analysis of the Poultry Economy

One of the important analytic results of any econometric model is the impact effects. Tables 2 and 3 present reduced-form elasticities for both short- and long-run models. The elasticities give the percentage change in selected endogenous variables as a result of a 1% change in various exogenous variables. Elasticities are used since reduced form multipliers are difficult to interpret due to dimension problems. The long-run elasticities give the impact of a sustained change over several periods in any exogenous variable. Since lagged variables (mainly prices) play a significant role on the supply side, the long-run multipliers are of considerable interest.

Table 1. Actual (A) and Predicted (P) Percentages of Change in Selected Endogenous Variables, 1970–73

	TPBC		*TPT*		*RPC*		*RPT*		*WPBC*		*FPT*

PFISH	0	0	0	0.30	0	0.30
XBC	0	0	0.14	0.07	0.19	0.06

Table 2 reveals the overall structure of the model. Since supply relations contain mainly lagged variables, there is very little short-run sensitivity on the part of these relations. The price (or demand) side of the model is quite sensitive to demand "shifters" such as income and substitute meat prices. Consider, for example, the demand relation for broilers, written for expository purposes in double log form as

$$(1)\quad ZC = TCCBC^{-0.82}\, ZBEEF^{0.15}\, ZPORK^{0.35}\, ZAO^{-1.37}\, ZWPCEB^{0.23},$$

which in view of the definition ($ZC = RPC/PCENDS$, etc.) can be written as

$$(2)\quad RPC\text{-}TCCBC^{-0.82}\, RPB^{0.15}\, RPP^{0.35}\, PAO^{-1.37}\, WPCEB^{0.23}\, PCENDS^{1.64}.$$

The elasticity of *RPC* with respect to *PCENDS* of 1.64 is simply the first round effect. This increased price for broilers then increases the demand for other chicken and turkey, in turn causing increases in *RPT* and *WPCEB*. The increase in *WPCEB* causes a "second round" increase in *RPC*. Since the elasticity of *WPCEB* with respect to *RPC* is 1.67, the total increase in *WPCEB* will be 2.74 (1.67 × 1.64). This increase of 2.74% will then cause a second round increase in *RPC* of 0.63. Hence, the first and second round effects so far are 2.27. Before going to the third round, it should be noted that increases in *WPBC* (as a result of increases in *RPC*) will increase supply and hence tend to lower *RPC*. At each successive round, these effects become smaller and smaller until they vanish numerically and a solution is reached. Table 2 gives the final outcome of the cumulative total of these first, second, third, and so on, round effects, which in the case of *RPC* is 2.34. The big impacts are caused by changes in *PCENDS* and *PAO*. In the long run, increases in prices call forth a supply response, which in turn tends to dampen prices. Hence, the long-run reduced-form elasticities for the price variables tend to be lower than their short-run counterparts, while the opposite is true for the quantities.

To continue the above example, the 1% increase in *PCENDS* that caused a 2.34% increase in *RPC* in the short run also caused *WPBC* to rise by 2.84%. In the next time period, the increase in *WPBC* causes an increase in *TPBC* of 1.02% (2.84 × 0.36). This increase in production will increase supply, which will, through the demand relation, lower *RPC* by 0.84% (1.02 × 0.82). These effects produce a second year solution, which is then fed in as a lagged endogenous variable into the third year solution and so on, until once again the changes vanish numerically. The cumulative sum of all of these yearly changes are the long-run elasticities, which in the case of *RPC* − *PCENDS* is

Table 3. Long-Run Reduced Form Elasticities

1.59. Tables 2 and 3 are a clear portrayal of this self-equilibrating mechanism, which is characteristic of agricultural products whose supply responds to lagged product prices.

It is now possible, using the results contained in table 2, to analyze the causes of the substantial rise in broiler and turkey prices in 1973. Taking the elasticities for the major exogenous variables and multiplying each times the percentage change in that variable gives the contribution of each variable to the overall price increase in 1973. Tables 4 and 5 present this decomposition analysis for retail broiler and turkey prices, respectively.

Table 4 indicates that, in the case of broiler chicken, the effects of all exogenous variables except beef, pork, and fish prices would have resulted in a price increase of 10.2 percentage points. The remaining 34.1 percentage points of the 44.3% increase was accounted for by increases in beef, fish, and (mainly) pork prices. Hence, three-fourths of the price increase for broilers was a result of increase in prices of substitute meats. Increases in fish prices are due mainly to supply problems that appear unrelated to current economic problems, mainly the time required to build new capacity in the industry and increase worldwide competition for fish. The large increases in pork prices (33% in 1973) are due in large part to the effect of decreases in the hog-corn ratio in 1971 and 1970. During those two years, the ratio of hog prices at the farm level to the price of corn fell 25.3% and 6%, respectively. Based on a study by Heien, the effect of these price-ratio declines accounted for a substantial portion of the decline in hog slaughter in 1973. The same is true for beef production, although in that case increases in the current price of feed grains were equally influential. Increases in the current price of feed grains were equally influential. Increases in feed costs in 1972 were largely responsible for the decrease in broiler production in 1973. It is also true that the very large increases in feed costs in 1973 had some effect on that year's production, although the statistical estimates failed to show any significant current year effect.

Decreases in the supply of beef (−4.6%), pork (−7.3%), and chicken (−2.2%) accounted for a substantial price increase through the "own price" effect. Based on calculation of this model and those for pork contained in Heien and for beef in Heien and Matthews, the supply reduction (of beef, pork, and chicken) due to effects of lagged price ratios accounted for 14 percentage points of the increase in broiler prices. The general inflationary pressures (money income and the price of all other goods) accounted for an additional 14.6 percentage points in broiler prices. The increase in fish prices resulted in a 4.6% rise. Of the remaining 11%, −5.6 percentage points are due to "time." The residual, 16.7 percentage points, may be ascribed to the effect on the demand for broilers of increased beef and pork prices, which were themselves the results of increased broiler prices. In other words, as beef prices increase due to short supplies of beef, the demand for broilers shifts, resulting in increased broiler prices. These increased broiler prices in turn raise the demand for beef again, resulting in further beef price increases, which then further raise broiler prices through their effect on broiler demand. The year 1973 was perhaps the only time in the postwar U.S. economy when the supplies of all three major protein items shifted downward simultaneously, thus making the usual substitution among meat and poultry extremely difficult. If one accepts the above analysis, then the role of current feed prices is considerably less than commonly thought. While it is true that increased feed costs do affect beef supplies (since cattlemen can bypass feed lots if corn prices are too high), their effect on broiler and pork supply is much less in the current period. Also not mentioned above (because of its nonquantifiable nature) is the impact of the 1973 price freeze on meat and poultry supplies. Unfortunately, the freeze effects are forever confused with the feed-cost increases and a sorting out of the two appears unlikely.

Projecting Performance of Farm Supply Retailing Firms Using Simulation Techniques

E. M. Babb and L. A. Lumpkin

Previous research used experimental gaming in a laboratory setting to test hypotheses about business behavior of firm managers as subjects (Babb and Bohl 1974). Subject managers were from midwestern farm supply retail outlets. This paper analyzes the implications of the behavior observed in the Babb and Bohl gaming experiments for future performance and organization. The objectives are to project which types of organizations are most likely to survive and grow in various competitive environments and to explore the implications of projected performance measures for firms in the industry and for farmers. The focus of this research is on the economic consequences of pricing decisions made by subjects in the gaming experiments. The means and standard deviations of price decisions made by managers from different types of organizations and under different competitive environments imposed in the Babb and Bohl experiments are the basic inputs for the simulator used in this research. The simulator provides longer run implications of repeated price decisions observed in the gaming experiment.

Procedures

The management game used for experimental gaming was redesigned as a simulator (Babb and Bohl 1969a, b). Since the focus was on the eighteen price decisions in the original experiment (prices for feeds, fertilizers, grains, and services), decision rules were developed to handle the twenty-three nonprice decisions. These decision rules were applied uniformly in our analyses, which had the effect of holding nonprice decisions constant. The simulator was made stochastic by incorporating a random number generator to develop price distributions for repeated trials, given the means and standard deviations of prices in the gaming experiment. Procedures were incorporated in the simulator so that random walk experiments could be performed.

Experiments were performed with the simulator using two treatment effects, type of organization and degree of price competition. Subjects from experimental gaming were classified into seven categories based on size, type of ownership, and number of retail outlets as follows: (*a*) independent proprietorship with single retail outlet and annual sales less than $600,000, (*b*) independent proprietorship with single retail outlet and annual sales of $600,000 to $1,400,000, (*c*) independent proprietorship with single retail outlet and annual sales over $1,400,000, (*d*) independent proprietorship with multiple retail outlets and annual sales over $1,000,000, (*e*) cooperative with multiple retail outlets and annual sales of $700,000 to $2,500,000, (*f*) cooperative with multiple retail outlets and annual sales over $2,500,000, and (*g*) cooperative with single retail outlet and annual sales of $1,000,000 to $3,500,000. The hypothesis to be tested was that projected performance would be the same for managers from the seven types of organizations.

In the experimental gaming study, Babb and Bohl set the cost of goods sold and the average price of products sold by subjects' competitors, i.e., the researchers acted as competitors so that all subjects faced the same competitive environment during a particular decision period. Three levels of price competition were imposed by Babb and Bohl representing situations of low, normal, and high gross margins. These margin levels were used in experiments with the simulator. The hypothesis to be tested was that projected performance would be the same under different competitive environments.

Experiments were conducted with the simulator where a replication refers to a one-year decision period under the specified combination of treatments. The first type of experiment involved fifty independent replications for managers from seven types of organizations under normal margins, under low margins, under high margins, and under the combination of margin situations used in the prior study.[1] The second type of experiment used fifty independent replications of the three to five most

E. M. Babb is a professor of agricultural economics at Purdue University, and L. A. Lumpkin is an operations research assistant at Land O'Lakes Cooperative.

Indiana Experiment Station journal paper 5921. Glenn Nelson, John Marten, and anonymous *Journal* reviewers provided constructive suggestions for this paper.

[1] The sample size of fifty was selected prior to conducting experiments with the simulator on the basis of standard deviations from the previous research, a confidence interval of 95%, and desired interval lengths. Subjects in the previous research made six sets of decisions in sequence. For each set of decisions, they faced various combinations of low, normal, or high margins that were balanced over the sequence of six decision periods; that is, subjects did not face low margins for all products in the game during one decision period. The simulation experiment that refers to the combination of margins used in the previous study duplicated the combinations used earlier.

[a] Types of organizations are identified as (a) through (g) as in text.
[b] All differences among group means significantly different at the 0.01 level of probability.
[c] Lines below the ranks of types of organization indicate that the means for these types are not significantly different at the 5% level of probability.

viable types of organizations under normal margins.[2] The third type of experiment involved twenty independent replications of a random walk situation covering ten decision periods by all seven types of organizations and by the most viable types of organizations, under normal margins.[3]

The performance variables (simulator output) used in subsequent statistical analyses included return on investment, profit, profit as a percent of sales, total sales, operating expenses as a percentage of sales, and gross margins for feed, fertilizer, and grain merchandizing. A one- or two-way analysis of variance (ANOV) was used to analyze performance variables, depending upon the design of the specific experiment. If the ANOV revealed significant differences[4] in performance variables among types of organizations, the Student-Newman-Keuls multiple range test was used to rank these categories.

[2] The selection of the three to five most viable types of organizations was based on the criteria of highest profits and returns on investment in simulation experiments, which included all classes of organizations.

[3] For the random walk experiments, the starting prices were based on the average of prices established by managers from each of the seven types of organizations in the previous research. Cost of goods sold was held constant throughout the random walk. Given the standard deviations from the previous study, the random number generator created the distribution of prices for that period. Prices for the second year were based on averages of prices in the first, and the random number generator then created prices for the second year and so on through ten periods. Thus, prices for different products could drift up or down over time.

Results

The first three experiments included all types of organizations under low, normal, and high margin environments. Differences in all performance variables among types of organizations were highly significant in each of the three experiments (table 1).[5]

[4] The F-value was significant at the 5% level of probability.

[5] Results for only the experiment using normal margins is in-

Table 2. Analysis of Variance Results for Performance Variables Using Two Treatments

Performance Variable	ANOV F-Values: Competitive Environment Effect*	Organizational Effect*	Interaction Effect
Return on investment	174	92	1.45
Profit as % of sales	154	107	1.34
Profit	176	90	1.31
Total sales	96	53	1.16
Operating expenses as % of sales	528	71	1.10

* Differences among group means for all performance variables were significantly different at the 0.01 level of probability.

In general, firms in organizational classes *c*, *d*, *e*, and *g* were most profitable and had the highest gross margins for feeds and fertilizers. This was largely due to cooperative organizations taking a lower margin on grain and higher margins on feed and fertilizer, compared to proprietary organizations. Firms in organization classes *a* and *b* generally had higher expenses as a percentage of sales, which partly accounted for their lower profitability. The most profitable groups did not necessarily experience the highest sales. From an economic standpoint, the results show important differences among types of organizations with respect to profitability measures. Differences of 1% to 2% in return on investment over time may affect survival.

The particular combinations of margin levels used for the six decision periods in the previous research were used as input to the simulator to obtain response surfaces for both types of organization and competitive environment. Both of these factors were highly significant (table 2). The interaction term for these factors was not significant, indicating that the relative performance of managers from different types of organizations was stable among different competitive environments. Ordinal rankings of types of organization on the basis of performance variables were essentially the same as in the experiments with low, normal, and high margins. This indicates consistency in performance among types of organization with variation in level of margins and with combinations of margin levels.

On the basis of the previous experiments, organizational classes *c*, *d*, *e*, and *g* were selected as the most viable, and the experiment with normal margins was repeated using only these four groups. There were still significant differences in performance variables among these four groups, but most of the rankings were not in completely separated groups (means that were the basis for ranking were not significantly different) as in the earlier experiments (table 3). Furthermore, the economic impact of differences in performance among these four types of organization is probably not important in terms of their relative success or survival.

The ten-period random walk experiment for all types of organizations under an environment of normal margins was replicated twenty times. Because of autocorrelation in performance measures among the ten time periods, ending net worth (sum of profits over ten periods) for each of the twenty trials was used as the performance variable. There were significant differences in ending net worth among types of organizations, and the same types of organizations (*c*, *d*, *e*, and *g*) that were most profitable in earlier experiments had the highest net worth. There was a tendency for prices to decline during the ten-period random walk as a number of managers in the previous study adopted a policy of pricing slightly below their competitors. This behavior was reflected in the results of the simulator. The ending net worths of the four most viable types of organizations were not significantly different in the experiment including only those groups.

cluded, as the results for high and low margins show an identical pattern. Of course, the level of profitability was higher or lower in these situations compared to normal margins.

Conclusions and Implications

The null hypothesis that performance would be the same for managers from the seven types of organizations was rejected in all experiments for all mea-

** Differences among group means significantly different at the 0.01 level of probability.

sures of performance. The experiment using combinations of margins was the basis for rejecting the null hypothesis that performance would be the same under different competitive environments. This was further supported by important differences in performance among the experiments with low, normal, and high margin levels. The null hypothesis that performance would be the same for the three to five most viable types of organizations was rejected, but the economic importance of these differences is probably not important to their survival. In fact, there were no significant differences in the ending net worth of the most viable groups in the random walk experiment.

If the types of organizations identified as the most viable in this research are the ones that survive and grow, the future organization and structure of farm supply retail outlets will change.[6] The current balance of firms by types of ownership is not projected to change, as two of the most viable groups were cooperative and two were proprietary. But types of organizations projected as the most viable had either large single retail outlets or had medium- or large-size multiple retail outlets. This implies that retail outlets in the industry will become more concentrated over time. The results are consistent with the rapid decline in the number of smaller firms that is taking place. The results do not imply the complete disappearance of firms in a particular type of organization. There was at least one firm in the poorest performing group that performed at least as well as the average performance in the most viable group.

Part of the poor performance of smaller firms could be attributed to their lack of control over operating expenses. Beyond this, managers from the smaller firms did not understand how their customers responded to price differences and the impact of prices established by competitors. They thus established inappropriate price policies in the gaming experiment. Educational efforts with smaller firms may improve their performance and viability.

Fewer and larger firms will increase the distance farmers travel to purchase inputs and to market grain. Farmers may pay higher prices for purchased inputs. In the case of feeds and fertilizers, firms in the most viable group charged higher prices, but there was an erosion of prices even among these firms in the random walk experiment. Furthermore, in the real world, there may be economies of size for the larger firms or those with multiple retail outlets that were not built into the simulator, and this could temper some of their higher prices. Differences in prices of feeds, fertilizers, and grains among different types of organizations suggest that it is advisable for farmers to compare prices.

In general, the decisions made by managers did not generate returns on investment that would attract large amounts of capital to the industry. Improved decisionmaking may be necessary to attract capital if industry expansion or renovation is needed.

[*Received June 1975; revision accepted November 1975.*]

[6] The likelihood of such a change is reinforced by the fact that the previous research did not detect significant differences between the behavior of managers in a laboratory setting and in real life.

Returns to Information: An Addendum

David L. Debertin, Robert J. Rades, and Gerald A. Harrison

A 1975 *Journal* paper by the authors (Debertin et al.) utilized a computerized management game to measure the returns to information for Indiana corn and soybean producers. Results indicated a rather substantial return to information. However, estimates in the paper have been questioned by agricultural economists at Purdue, the University of Kentucky, and elsewhere because participants in the laboratory experiment were students, not experienced farmers. In response to these criticisms, a second experiment was conducted using experienced farmers as participants. The identical management game (Debertin, Harrison, and Rades) and a similar experimental design were used in both experiments.

Farmer Participants

Participants in the laboratory experiment consisted of thirty-nine farmers from six central Indiana counties. Farmers in the experiment represented a substantial diversity in age, education, and size of commercial operation (table 1). An honorarium of $50 was paid to each farmer participating in the experiment. In addition, prizes of $25, $15, and $10 were given to the three farmers generating the most profits in each group.

The high cost of the experiment (approximately $100 per participant) made it necessary to limit the sample size to approximately forty participants. Results from the earlier study revealed a great deal of within-group variability in the profit performance of participants. Hence, it was decided to divide the farmer participants into only two groups. All participants in this experiment were provided with feedback from the previous decision(s).

Each farmer made a predecision prior to the main experiment. The predecision ensured that the farmers were familiar with the gaming procedures and served as the basis for assignment of farmers to the two treatment groups (with and without research information). Farmers were ranked according to predecision profits and assigned to the treatment groups following the same procedure used in the earlier study with the students (Debertin et al.).

D. L. Debertin is an assistant professor of agricultural economics at the University of Kentucky; R. J. Rades is an assistant professor of agricultural economics and G. A. Harrison is an associate professor of agricultural economics at Purdue University.

The authors are indebted to Emerson Babb, John Kadlec, and George Lee for helpful comments. Eugene Matzat assisted with the laboratory experiment. Journal paper number 6115 of the Purdue Agricultural Experiment Station.

Table 1. Characteristics of Farmer Participants

Characteristics	Mean	Range
Age (years)	41	21–60
Education (years)	12.6[a]	10–16
Total acres farmed	806[b]	250–1800
Total acres corn	440	75–1200
Total acres soybeans	217	0–850
Days worked off farm	8.5	0–90

[a] Students participating in the earlier experiment had a mean educational level of 15.6 years with a range of from 13.5 to 18 years.
[b] Most of the students participating in the earlier experiment came from farms throughout Indiana. A few came from states such as Illinois and Ohio. Students' farms averaged 449 acres and ranged in size from 0 to 1,640 acres. Only five students were not reared on farms. Approximately 90.4% of the students had been involved in corn or soybean production.

Statistical Results

Mean profits generated per year for the two groups of farmers over the five years of game operation are presented in table 2. The earlier data from the experiment with the students is also presented for comparison. The data in table 2 reveal that the farmers did not do as well at managing the simulated farm as the students. Farmers without information averaged $8,672 net returns per year over the five decision periods (years), and students without information averaged $11,935 net returns per year over the five decision periods, a difference of $3,263. Farmers with information averaged $9,724, while students with information averaged $15,866, a difference of $6,142. Moreover, the return to information for the students was $3,931 per decision period, while for the farmers the return to information was $1,052.

A two-way analysis of variance of the data is presented in table 3. Information had a significant positive impact on profit levels in three of the five decision periods. Students were able to generate significantly greater profits with the game than were farmers in four of the five decision periods. A significant F-ratio on the interaction effect would suggest that students with information were better able to decode and use information in a decision-making context than were farmers (Welch). How-

Table 2. A Comparison of Profits Generated with the Game for Students and Farmers

Year (Decision Period)	Farm Management Students: Without Research Information $n = 17$	Farm Management Students: With Research Information $n = 16$	Experienced Farmers: Without Research Information $n = 20$	Experienced Farmers: With Research Information $n = 19$
1	−2,292	−504	−2,746	−3,897
2	14,094	19,316	9,801	12,507
3	17,787	25,267	12,482	14,909
4	4,099	7,177	−152	1,583
5	25,990	28,073	23,977	23,519
Average of 5 years	11,935	15,866	8,672	9,724

ever, the interaction effect was significant in only one of the five decision periods. Hence, it is apparent that information has a significant impact on profit levels generated with the game. Students were able to generate significantly larger profits with the game than were farmers.

Differences in the Behavior of Farmers and Students

Why did the farmers perform differently than the students? One explanation for the observed differences in profit levels between students and farmers is that these differences may reflect marginal returns to an education in a college of agriculture. The "no-information" students may have been exposed to information useful in making game decisions in formal course work prior to the time the experiment was run.

A second, perhaps more troublesome, explanation is that the students, having worked for nearly four years under academic pressures of a university environment, adapted more readily to the abstractions of the simulated (laboratory) environment than did the experienced farmers. This line of reasoning would seem to suggest that the students were not in fact better farm managers but rather were merely better able to play the game.

A third explanation for observed differences in the performance of the farmers and the students is that the information (given to some of the participants and used as a basis for deriving coefficients and relationships within the game) may not be a correct mirror of the real world. Students may accept the information at face value. The farmers may be conditioned to believe that not all information (even that put out by university colleges of agriculture) is correct. Farmers may indeed be superior to students in finding errors in research and extension information.

A major research effort now needs to be directed toward an analysis of the extent to which the behavior of participants in computerized gaming ex-

Table 3. Analysis of Variance of Profits for Students and Farmers

Decision	Condition	F-Ratio	Significance
1	Information—No Information	0.02	Nonsignificant
1	Students—Farmers	1.59	Nonsignificant
1	Interaction	0.97	Nonsignificant
2	Information—No Information	5.94	0.01
2	Students—Farmers	12.06	0.005
2	Interaction	0.63	Nonsignificant
3	Information—No Information	10.57	0.005
3	Students—Farmers	28.07	0.005
3	Interaction	2.98	0.05
4	Information—No Information	2.23	0.10
4	Students—Farmers	9.66	0.005
4	Interaction	0.18	Nonsignificant
5	Information—No Information	0.18	Nonsignificant
5	Students—Farmers	3.74	0.05
5	Interaction	0.57	Nonsignificant
Total	Information—No Information	4.50	0.025
Total	Students—Farmers	17.28	0.005
Total	Interaction	1.65	Nonsignificant

Note: The model was $Y_i = \alpha_i + \beta_1 D_{1i} + \beta_2 D_{2i} + \beta_3 D_{1i} D_{2i} + \epsilon_i$, where Y_i = mean profits for the ith participant, $D_{1i} = 1$ if participant was a student (0 otherwise), $D_{2i} = 1$ if participant received information (0 otherwise), and $\epsilon_i \sim N(0, \sigma^2)$.

periments is consistent with the behavior of farm managers in the real world. Such an experiment might focus not only on the managerial decisions farmers make under controlled laboratory conditions utilizing a management game but also on the managerial decisions the farmers actually make in the real world. A greater degree of experimental realism would be obtained by incorporating additional managerial decisions dealing with other aspects of crop production. Intensive questioning prior to the laboratory experiment would enable researchers to determine the actual decision made by the farmer with regard to key managerial practices in crop production. These data would then be compared with data subsequently gathered within the laboratory experiment.

A Note on the Social Returns to Private Research and Development

Willis L. Peterson

The seminal work of Schultz and Griliches (1958, 1964), along with more recent efforts by Ayer and Schuh, Evenson (1967, 1974), Peterson (1967, 1971), Schmitz and Seckler, and others, have shown that investment in agricultural research has yielded a high social return. Although private investment in agriculturally related research and development (R&D) has been taken into account in many of these studies by adding rough estimates of private research to the public expenditures, there is virtually no independent information on the social returns of private R&D relating to agriculture. (This is probably due to a lack of data on private R&D.) It is certain that the expected private rate of return to this investment is at least as great as the expected private rate of return to alternative investments, else it would not be carried out. But is the social return to private R&D high enough to justify this investment from society's point of view?

I shall argue in this note that in spite of the lack of empirical evidence on the social returns to private R&D, we can be assured that, as long as R&D is privately profitable, it is also socially profitable. The key to the argument is the excess of social over private returns. This is not to say that private investment decisions will result in a socially optimum level of R&D, particularly basic research. It is recognized that because of the "public goods" nature of the information generated by basic research, most of this work has to be publicly funded. As Nelson points out, "the fact that industry laboratories do basic research at all is itself evidence that we should increase our expenditure on basic research" (p. 304). Hirshleifer takes a somewhat different view, arguing that there may be overinvestment in private information-gathering activities if the information remains private "in the sense of being purely redistributive, not leading to any improvement in productive arrangements" (p. 573). However, in the case of the farm-supply industry, it will now be argued that private R&D yields a private return only if it results in an "improvement in productive arrangements," i.e., yields a social return by increasing agricultural output.

Willis L. Peterson is a professor in the Department of Agricultural and Applied Economics at the University of Minnesota.

Private and Social Returns Defined

It will be useful at the outset to define the meaning of "private" and "social" returns as they relate to private R&D. Private returns are defined as the additional net earnings that the firm is able to capture by investing in R&D. Additional net earnings in this case are defined as the additional sales that result from R&D minus associated production and marketing costs that may be required to produce and market the products or services that result from R&D. Of course, the associated costs do not include the R&D expenditures. In the context of cash flow analysis, the R&D costs are the cash outflows, while the additional net earnings (added gross sales minus associated costs) represent the net cash inflows.

Investment in R&D is profitable for the firm if the discounted present value of the stream of added net earnings is equal to or greater than the accumulated R&D expenditures using the appropriate discount rate, such as the rate of interest on borrowed funds or the opportunity cost of capital on equity funds. This is not to say that all private R&D turns out to be profitable. No doubt all firms that conduct R&D have invested in projects that have turned out to be unprofitable. Indeed, it is quite possible that during a specific period the entire R&D effort of certain firms have turned out to be unprofitable (Mansfield). In this sense, R&D is no different than any other investment. No one can be certain of the payoff until the returns have come in. Over the long run, however, the profitable projects must more than offset the unprofitable ones, else the firm will discontinue R&D or go out of business entirely.

In measuring the rate of return to public research, the social returns have been defined as the value of additional output that is forthcoming because of the research. Traditionally, the social returns have been measured as the change in consumer surplus or area between the old and new supply curves bounded on the top (or right) by the demand curve (Griliches 1958, Peterson 1967). It would seem logical to define the social returns to private R&D in the same manner. Therefore, let us define the social returns to private R&D as the value of additional agricultural output that is forthcoming because of the R&D, as measured by this area of consumer surplus.

Why Social Returns Exceed Private Returns

In order for farmers to adopt new or improved inputs made possible by private R&D, the value of marginal product (VMP) of the inputs in terms of agricultural output must be greater than their respective prices. In other words, the adoption of new inputs must reduce production costs from what they would otherwise be. If not, farmers would continue to use the old inputs or technology. The prices of new inputs must include not only a return to the R&D that made possible the production of the inputs but also a recoupment of R&D costs that did not result in a saleable product.[1] This is the only way private firms can capture a return to their R&D. Input prices must exceed their pure production costs by at least enough to provide a normal return on the investment in R&D, otherwise the R&D will not be done.

As farmers adopt the new, more productive inputs and unit costs begin to decline, the supply curve of agricultural products shifts to the right as illustrated by the shift in supply from S_0 to S_1 in figure 1. It is this shift in the supply curve that gives rise to the conventional measure of consumer surplus or social returns represented by the single line shaded area in figure 1.

It is important to recognize, however, that the reduction in production costs to farmers and the resulting shift in supply from S_0 to S_1 does not reflect the full increase in output that has resulted from the R&D. Part of the increase in output, marginal physical product (MPP), stemming from the use of new, more productive inputs is covered up by that part of the price increase that represents a private return to private R&D. Thus, the shift in supply as measured by the reduction in production costs understates the full contribution of private R&D to output.

A simple numerical example illustrates the point. Consider one variable input whose MPP (at a given quantity) doubles because of R&D. Assume the price of the input rises by 50% but half of the price increase is a return on the R&D that made the increase in MPP of the input possible. The percentage decrease in marginal cost (shift in the supply curve) is 25% when the private return to the R&D is included in the price. But the shift in supply would be 37.5% if the input price did not contain a private return to the R&D. The example is summarized in table 1.

To treat private R&D the same as public research from the standpoint of measuring social returns, then that part of the contribution of private R&D that reimburses the private firms for the cost of the R&D should be included, shown by the double-line shaded area in figure 1. Hence, the relevant supply curve is S_2 in figure 1, and the area of

[1] Part of these R&D costs may be failures and part the nondirected or "basic" research conducted by the firm.

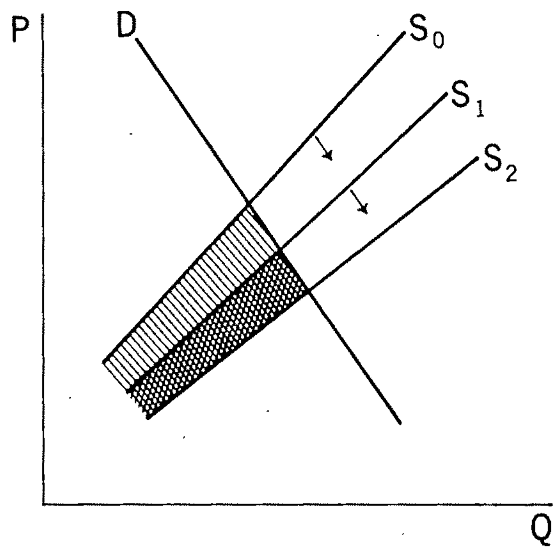

Figure 1. Social returns to private R&D

consumer surplus should include both the single- and double-line shaded areas. In terms of the above example, the relevant supply curve would be that which exhibited a 37.5% shift rather than the 25% change.

If the consumer surplus represented by the double-line shaded area in figure 1 is neglected, it amounts to double counting the cost of private R&D when assessing the social rate of return to this investment. The cost would be included once on the cash outflow side and would appear again on the return side as a reduction in cash inflow (social returns). Such a procedure would be comparable to subtracting the cost of public research from its returns before matching its costs against returns in order to compute a benefit-cost ratio or internal rate of return. Of course, this procedure is not done in evaluating the profitability of any investment.

Because the private returns to private R&D are included within and are a subset of the social returns, for society as a whole the social returns to private R&D must be greater than the private returns.[2] Unless the marginal cost of producing the output using the improved input is lower than the

[2] Externalities aside. However, it is not evident that externalities are more prevalent in private than public R&D.

Table 1. Illustrating the Effect of R&D on Marginal Cost (MC)

	MPP	Input price	MC	% ΔMC
Initial situation	100	$100	$1.00	—
Price includes R&D cost	200	150	0.75	−25
Price excludes R&D cost	200	125	0.625	−37.5

marginal cost of production using the traditional input, the new input will not be adopted, and there will be no private or social returns. In other words, in order for there to be private returns, the total area between S_0 and S_2 in figure 1 must be greater than the area between S_1 and S_2. Otherwise, there will be no incentive for farmers to adopt the input.

This same reasoning applies to the case where R&D reduces the cost of producing an input of constant quality, e.g., nitrogen fertilizer. Even though the price of the input is reduced because of R&D, the price still must include a return to the R&D in question. Hence, the observed shift in supply of agricultural products that occurs because of the reduction in costs understates the full contribution of the R&D to output.

Although the private returns to R&D are smaller than the total social returns, the ratio of private to social returns can be expected to vary between inputs and between points in time. A new input that does not have close substitutes and therefore exhibits a relatively inelastic demand (facing the supplier) should yield higher pure profits and a higher private relative to social return, other things being equal. However, over the long run, as more and closer substitutes become available and pure profits are eroded away, the private returns should diminish relative to the social returns. Also, the ratio will depend on the point in time (relative to the introduction of the input) the returns are evaluated. The more time that has elapsed and the greater the number of substitutes that become available, the lower should be the private relative to total social returns. Indeed, after a long period of time has elapsed, it is not unreasonable to believe that the annual private returns to many innovations become negligible, while their social returns continue on indefinitely. Such is the nature of economic growth.

A Brief Assessment of Extension Land Use Educational Publications

Craig L. Infanger and A. Frank Bordeaux, Jr.

Land use policy is once again a focus of attention for many agricultural economists. Extension educational programs in this area have produced a large number and variety of publications related to land use. A request for available printed materials on this subject was sent to the fifty extension directors by the authors. The purpose of this paper is to briefly review these publications, assess the strengths and weaknesses of the literature, and offer brief constructive criticism.[1]

This review of extension's land use publications is appropriate for three reasons: (*a*) printed media are an important channel of communications between extension professionals and their clientele, and every effort to upgrade and improve publications should be made; (*b*) cross-fertilization between extension programs improves the total educational effort; and (*c*) exchange of publications is an important method of communication among extension professionals, and this article hopes to foster this communication.

Extension's Land Use Educational Publications

Forty-one extension directors responded to a request for available printed materials in land use. Four of these states—Tennessee, Georgia, Maryland, and Massachusetts—had publications in process at that time. Materials supplied by six states—Arizona, Hawaii, Nevada, New Mexico, Rhode Island, and Wisconsin—were not considered educational publications in the same sense as the remaining materials.[2] Subject matter is the only common characteristic of the publications from the remaining thirty-two responding states. The diversity in format and content is remarkable. However, three approaches seemed to be used most often.

North Carolina's educational "package," *Land Use Planning in North Carolina*, illustrates the package approach and consists of a coordinated series of pamphlets on land use.[3] Another "package" of eight topically coordinated pamphlets is available from Texas and is unique in the sense that it provides in the first pamphlet a historical perspective for the development of land use patterns in the state. Wyoming also uses a "package" format to produce *Series Six*, a set of six very brief (two-page) treatments of related aspects of land use and community planning.

Several states provide land use planning information in extension bulletin or circular form. One of the most comprehensive of these is *Using Comprehensive Planning in Montana* (House). Other bulletins include *A Guide for County Land Use Planning: Colorado* (Davis and Sorensen), *Some Legal Aspects of Land Use Planning in the Mountain State* (Zagaris), and *Performance Standards: A Technique for Controlling Land Use* (Stockham).

Only one state uses the case study approach to land use education publications. Illinois has an educational package, *Illiville, Illinois: Planning Documents*, which consists of (hypothetical) annual reports from a city and a planning commission, a review of state laws, long-range plans, zoning ordinances, subdivision controls, and other related materials (Illinois Bureau of Community Planning). A modified case study approach was used in one publication coming out of Utah, *Workbook in Land Use Planning* (Germanow and Grimsely).

The remaining publications can be classified as potpourri. Various issues of several newsletters including *Trade Secrets*, (Mississippi Cooperative Extension Service), *Palmetto Economics* (Clemson Cooperative Extension Service), and *Kentucky Economics Topics* (Kentucky Cooperative Extension Service) have devoted issues to land use. In many cases, these newsletters appear to have become integral parts of educational programs. Numerous other types of publications address some specific subset of the land use issue in some detail. Examples of this are *Open Space Taxation* (Barron and Florea), *Transfer of Development Rights* (Chavooshian and Norman), and *Conservation Easements* (Liden).

Craig L. Infanger is an assistant extension professor and A. Frank Bordeaux, Jr., is an associate professor in the Department of Agricultural Economics at the University of Kentucky.

The authors wish to acknowledge the helpful suggestions and criticisms of Verne W. House, Leon E. Danielson, and the *Journal* editors and reviewers.

[1] Doubtless, we did not receive all the available printed materials. This is unfortunate but unavoidable because a few directors did not respond and others may have failed to forward all available publications. Although several omissions were detected by the authors, others may remain. In addition, the authors recognize that extension economists rely on information sources other than printed materials. However, these are beyond the purview of this article as are the research bulletins, seminar proceedings, and journal articles.

[2] Included in this group were publications on selecting home sites, research bulletins on land taxation, bibliographies, conference proceedings, and related state government documents.

[3] The North Carolina package has been adapted in whole or in part for use in Arkansas and South Dakota.

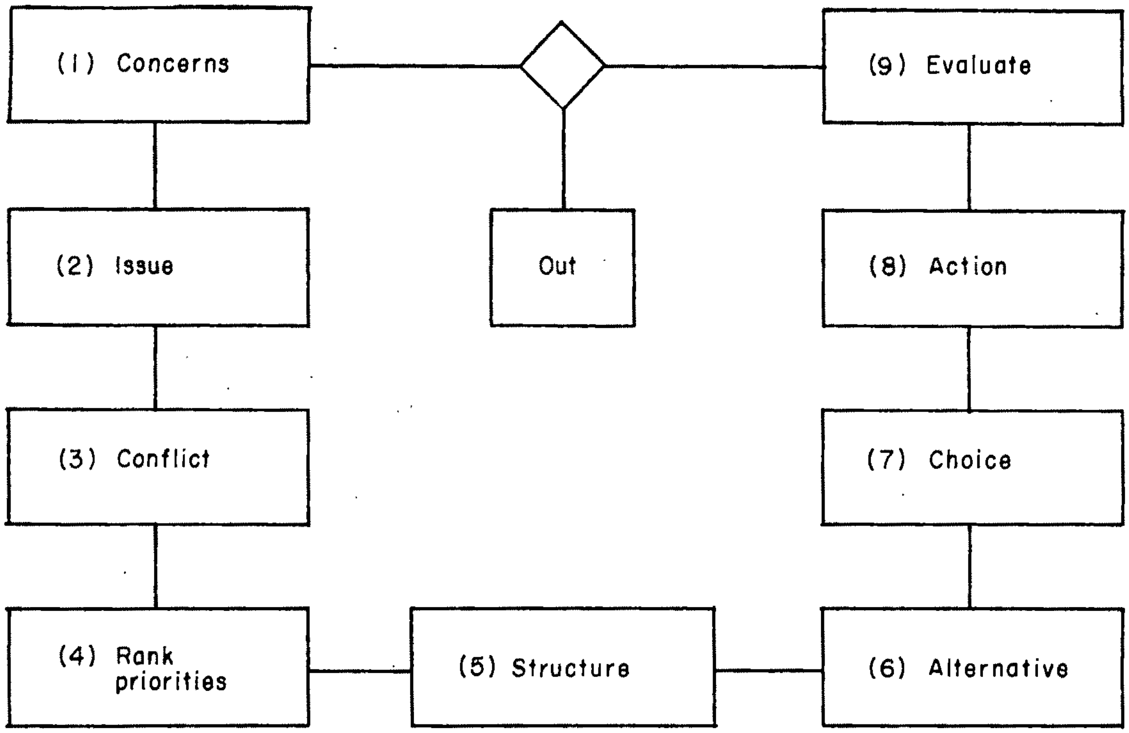

Figure 1. Issue cycle flow chart. Source: Gratto.

A Brief Assessment

Charles Gratto has developed a general framework that integrates the main features of the public affairs education process. The Gratto issue-cycle flow diagram is shown in figure 1. Participants in the resolution of a public issue such as land use planning generally begin at some point of concern (1). The search for resolution generates discussion that gives the issue (2) a name and defines it in action terms. Interests conflict (3), and debate is generated over priorities for resource allocations. The debate forces a ranking of priorities (4), and more objective and scientific knowledge defines the issue in more realistic terms. The structure (5) of the problem can be seen more clearly, although objective views of the issue do not converge. Policy alternatives (6) are defined, and participants evaluate each in terms of complex social and economic dimensions. Some public choice (7) is forthcoming, which is followed by action (8), implying either change or continuation of status quo. Finally, a period of evaluation (9) follows in which consequences and effects of the action are weighed. If the action generates "satisfaction," the cycle recedes; "dissatisfaction" causes the cycle to resume.

Intervention of public affairs education can occur at any point (cell). In terms of the land use issues, awareness education programs include information (publications) illustrating and defining the land use issue and outlining the historical perspective for the current controversy (cells 1, 2, and 3). Policy alternatives education programs provide information (publications) on the planning process, present land use control techniques, present federal and state legislation, and proposed new control techniques (cells 4, 5, and 6). Finally, consequence evaluation education programs focus on citizen involvement in public choice, effectiveness of land use controls, and implications of land use planning for various interest groups (cells 7, 8, and 9).

Classifications of Extension Publications

The various states' publications were classified into at least one of the educational categories (table 1).[4] Because educational intervention can come at any point in the issue cycle, it was not expected that every state would have materials in every category. It should, however, be reasonable to assume that for all states publications are available in some form for all categories.

Thirteen states have materials appropriate for intervention in the awareness phase of the issue

[4] The authors recognize there are numerous possible classification schemes and made the choice to utilize the Gratto framework. Also, it is recognized that the subject matter coverage of several of the publications extends over one or more categories. However, inclusion in only one category is based on the primary focus of the publication.

cycle.[5] One of the best of these publications is "Planning for Tomorrow's Communities" (North Carolina Agricultural Extension Service). The text begins with the warning: "The landscape around us has taken on new and controversial aspects under pressures from technological and social changes" (p. 1). Pursuing that theme, the land use policy issue is outlined for North Carolinians in terms of population growth, employment, land use patterns, and the planning and choices ahead. This type of information can assist people in defining more precisely their concerns about use and development of land resources.

While there are good examples of awareness-type publications that outline the problem and give some perspective, there is a paucity of information on historical development. Texas is the only state with a publication that traces the development of the present state land use pattern (Texas Agricultural Extension Service).

In the second phase of the issue cycle, the policy-alternatives educational effort, publications are abundant. Nineteen states have publications on the functioning of local planning agencies. Many of these provide a step-by-step explanation of the comprehensive planning and land use regulation process. For small group education, the Utah *Workbook in Land Use Planning* (Germanow and Grimsley) seems to be a particularly appealing document for use in this area.

Publications related to present control techniques are plentiful. The Wyoming *Series Six* covers zoning in two pages under the title, "Don't Talk to Me About Zoning." South Carolina has extensive and detailed examinations of both zoning law and subdivision control—a total of ninety-two pages (McLemore, Ledbetter). Between these extremes are numerous publications differing widely in emphasis and format.

Most of the print is devoted, justifiably we think, to the police power techniques of control—zoning, subdivision regulation, and building codes. Without much question these are the most familiar of land use controls. If there are important weaknesses in the coverage of zoning, we see these as standing out. First, there is virtually no mention of the

[5] The Extension Committee on Policy (ECOP) of the Extension Service has recently published some land use materials, *Land Resources Today*, of which pamphlet No. 1 addresses the problems, situation, and perspectives (USDA).

Model Land Development Code of the American Law Institute. This is intended as a replacement for the current state enabling legislation and could go a long way to improve inadequacies in local planning and zoning. Second, we do not think sufficient attention has been devoted to the political-legal problems of planning and zoning. A few pointers from Richard Babcock's *The Zoning Game* might prove useful in some publications.

On land use controls other than zoning, the available material is sparse. The state of Washington has a pamphlet on open space taxation (Barron and Florea). However, no treatment has been given to the "takings" issue, the use of public expenditures to control land use, or nonzoning (i.e., deed restrictions, covenants).

Several states have publications on state land use laws. The University of Arkansas, for instance, has published two "Guidelines" outlining statutory requirements for municipal and county planning, *Guidelines for County Planning in Arkansas* and *Guidelines for Municipal Planning in Arkansas*. Only a few states have published information on proposed federal land use legislation, mostly in newsletter form.

Policy alternatives are probably the most important segment of the second phase of the issue cycle. Yet, only eight states have publications that address one or more of proposed new land use controls. The work of most notoriety is New Jersey's "Transfer of Development Rights: A New Concept in Land Use Management" (Chavooshian and Norman). Transfer of development rights (TDR) is a modification of zoning law intending to facilitate markets for development rights to land. It is one of several alternatives to be put before clientele groups. One Oregon publication reviews some of the newer techniques for land use control (Pease and Stockham). Topics included in this publication are performance zoning, TDR's, conservation easements, windfall gains taxes, and public purchase-leaseback.

The third phase of the issue cycle, consequence evaluation education, is an area of increasing importance. Many states are initiating new land use controls. Extension should be actively engaged in providing feedback on the consequences and impacts of these new programs. The paucity of publications in this area suggests we may be doing otherwise.

With respect to citizen involvement in public choice about land, only six states have any publications in this area. None of these are evaluative in any sense. Some explain who is involved in the planning process and at what points citizen input is possible (desired?).

Very little critical evaluation of land use control effectiveness is available. Information on taxation is plentiful enough to provide the basis for a fair evaluation of taxation as a land use control. But what about zoning? purchase of development rights? conservation easements?

Implications of land use controls for agriculture and other groups is another topic addressed in weak fashion—brief mention is made in the North Carolina and Wyoming literature. No one has come forward to illustrate the trade-offs faced by farmers in the choice between preservation or nonpreservation of agricultural land. Similarly, there is little information about the shifting of property tax burdens under preferential assessment of farmland. These and other implications are important in matters of public choice.

Some Observations

From this review of extension land use educational publications, the following observations (challenges?) are offered. (*a*) The publications from many states seem to be a response to an immediate pressing land use problem. An example is *The North Dakota Farmer/Rancher Looks at Severed Mineral Rights* (Johnson, Beck, and Sillers), published in response to the increased activity in coal strip-mining. This type of immediate reaction is appropriate and positive but does not seem to be followed by or coordinated with systematic development of a "package" of materials useful among different clientele groups and over extended time periods. This would explain in part the reason why the greater numbers of publications are in the policy alternatives category rather than awareness education. This raises the question of whether or not there exists enough commonality between states and land use issues to permit reprinting and adaption from one extension program to another. Is it expecting too much to find materials developed in New England that are applicable in the Southwest? In general, the answer seems "No"; an excellent example is the North Carolina package that has been adapted by both Arkansas and South Dakota. A facilitating mechanism for sharing of materials between states might be the Functional Network in Land Use Issues sponsored by the Southern Rural Development Center. This Network is designed to bring together researchers and extension economists in an attempt to inventory the available literature, synthesize results, and present implications for action programs. It is still early but in the near future this approach can be more thoroughly evaluated. (*b*) Can extension do justice in awareness education without tracing the development and forces, social and economic, behind present land use patterns? We think not. What was done in *Texas Land Use* (Texas Agricultural Extension Service), in Raup's "Achieving Land Use in the Public Interest," and in the League of Women Voters' "Land Use: Can We Keep Public and Private Rights in Balance?" needs to be done for every state having an awareness education effort. Whether it is oil in Texas, irrigation in California, or coal in Kentucky, there have been important social and economic variables that have been prime

determinants of the dominant land use patterns of development. These ought to be brought into sharp relief against some of the new determinants: redistribution of property rights, expanding federal regulations impinging on land use, reversal in population centralization, and the amelioration of externality problems. (*c*) There is a clear need for additional effort in laying out the policy alternatives. In many cases, the public perceives the land use control issue as "zoning versus no regulation." This is an unfortunate situation but a challenging opportunity for the educator. As W. L. Gibson, Jr., has recently written:

> The problems involved in developing a workable land-use policy are not ones of zero-risks, zero-use conflicts, or zero-restraints on resource use. The problems are how to develop enough public support at the appropriate levels of government in which capability exists to choose among alternative courses of action consistent with present knowledge. Such public support can arise only from an enlightened public. (p. 2)

(*d*) Research now published or underway provides some information on the consequences and impacts of land use controls. This information, where available, needs to be digested, synthesized, popularized, and published for lay consumption. Where the information is not available, research should be initiated if only on an informal basis. This information is critical in regard to determining the extent to which commercial agriculture and rural areas will bear the burden of expanded land use controls: shifting property tax burdens, restrictions on acceptable uses, and increases in agricultural production costs.

Microeconomic Output Supply and Factor Demand Functions in the Agriculture of the Province of Taiwan

Pan A. Yotopoulos, Lawrence J. Lau, and Wuu-Long Lin

Normalized restricted profit functions have been employed in the empirical analysis of agricultural production by Lau and Yotopoulos in a cross-sectional study of farms in India. The objective of the present study is to apply the same methodology to the analysis of data from a cross section of farm households in the Province of Taiwan, Republic of China. Two features distinguish this study from the earlier one. First, the number of variable inputs is increased from one to four. Second, the hypothesis of structural change as between successive cross sections is tested. Such a test of structural change may be interpreted as a test of the stability of the estimated production function parameters.

The Normalized Restricted Profit Function

The production function for each agricultural household is assumed to be Cobb-Douglas in form. Four variable inputs, labor, animal labor, mechanical labor, and fertilizer, and two fixed inputs, land and fixed assets, are distinguished. The normalized restricted profit function (for a discussion of the normalized restricted profit function as applied here and its properties, see McFadden, Diewert, Jorgenson and Lau [1974a, 1974b], Lau [1975], and Lau and Yotopoulos)[1] is given by

$$(1)\quad \ln \Pi^* = \ln A^* + \alpha^*_L \ln q_L + \alpha^*_A \ln q_A + \alpha^*_M \ln q_M + \alpha^*_F \ln q_F + \beta^*_K \ln Y_K + \beta^*_T \ln Y_T + \sum_{i=1}^{7} \delta_i D_i,$$

where Π^* is restricted profit (current revenue less current variable costs), per farm, normalized by the price of output; q_L is the money wage per day normalized by the price of output; q_A is the money animal wage per day normalized by the price of output; q_M is the money mechanical wage per hour normalized by the price of output; q_F is the money price of fertilizer per kilogram normalized by the price of output; Y_K is the quantity of fixed farm assets in New Taiwan dollars; Y_T is the farm area in hectares; and D_i's are dummy variables corresponding to agricultural regions.

The demand for each variable factor of production is obtained, using Shephard's Lemma (for a derivation of Shephard's Lemma, see, e.g., Lau [1969]), by differentiating the normalized profit function with respect to the normalized price of that factor: $X_i = -\frac{\partial \Pi^*}{\partial q_i}$, $i = L, A, M, F$, which implies that

$$(2)\quad \frac{-q_i X_i}{\Pi^*} = -\frac{\partial \ln \Pi^*}{\partial \ln q_i} = \alpha^*_i,\ i = L, A, M, F,$$

where X_L is total labor days, X_A is total animal work days, X_M is total hours of mechanical equipment, and X_F is total quantity of fertilizer in kilograms.

From the definition of normalized profit the output supply equation may be obtained:

$$(3)\quad V = \Pi^*(q, Y) - \sum_i \frac{\partial \Pi^*(q, Y)}{\partial q_i} q_i.$$

Given any five equations of types (1) through (3), the sixth may be obtained from the normalized profits identity, $\Pi^* = V + \sum_i q_i X_i$. Hence, one can drop one of the six equations. We concentrate therefore on equations (1) and (2).

Estimates of all the parameters can be obtained from equation (1). Alternatively, one can estimate the parameters of the variable factors of production from equations of type (2). Under the hypothesis of profit-maximizing and price-taking behavior on the part of the farms, the parameters in equation (2) are equal to the corresponding parameters in equation (1). (For a derivation of this result, see, e.g., Lau and Yotopoulos.) This, then, provides the basis for an explicit test of the hypothesis of profit maximization. If the hypothesis of profit maximization is not rejected, we proceed, conditionally, to test two subsidiary hypotheses: constant returns to scale in production and absence of structural change.

Constant returns to scale implies that $\beta^*_K + \beta^*_T = 1$. (For a derivation of this result, see, e.g., Lau and Yotopoulos.) Absence of structural change implies that the estimated parameters of the nor-

Pan A. Yotopoulos is a professor, Lawrence J. Lau is an associate professor, and Wuu-Long Lin is a research associate in the Food Research Institute and Department of Economics at Stanford University.

The authors thank an anonymous referee for very helpful suggestions and Mr. Yoshimi Kuroda for computational assistance. Financial support from the Ford Foundation through grant No. 720-0432 and from the Center for Research in International Studies at Stanford University is gratefully acknowledged.

[1] In the last reference, the term "UOP profit function" rather than "normalized profit function" is used.

malized profit function are identical as between 1967 and 1968. A generalization of the Chow test is employed to test the hypothesis of the absence of structural change.[2]

The Data

The bulk of the data for this research was derived from Provincial Government of Taiwan, Department of Agriculture and Forestry, *Report of Farm Record-Keeping Families in Taiwan, 1967* and *1968*, hereafter referred to as the *Report*. This source was supplemented with data from Provincial Government of Taiwan, Department of Agriculture and Forestry, *A Report on Cost Survey of Agricultural Products, 1967* and *1968* and *Taiwan Agriculture Yearbook, 1967* and *1968*. A brief description of the data follows; more specific information is given in Yotopoulos, Lau, and Lin.

The basic data source provides information on household averages of about 400 farm households grouped according to five sizes of operation (from below 0.5 hectare to 2.0 hectares and above by 0.5 hectare steps) and eight agricultural regions. The number of observations available, therefore, is about forty for each year. The information includes the expenditures on the variable factors of production and the quantities of labor, animal labor, and mechanical labor. The wage rate is also computed from the *Report*. The animal labor and mechanical labor wage rates are computed from subsidiary sources. The computation of fertilizer price is rather involved and is detailed in Yotopoulos, Lau, and Lin. An output price index is constructed for each observation that takes into account the differential composition of output using subsidiary data at the hsien (or county) level.

Fixed farm assets are given in New Taiwan dollars and include investment in plant and live capital in the *Report*. From these two components, the fixed input component of farm assets are estimated. Cultivated land, which is reported separately for paddy land and dry land in hectares, is homogenized into paddy land-equivalents.

Statistical Method

Given the assumptions of profit-maximizing and price-taking behavior on the part of the farm households, the strong concavity of the production function in the variable inputs, and the short-run constancy of the quantities of fixed assets and land, the farm's decision variables are the quantities of output and the four variable inputs. The prices of output and the four variable inputs as well as the quantities of the fixed inputs are predetermined and not subject to change by the action of any one farm in the short run. Consequently, output, labor, animal labor, mechanical labor, and fertilizer are jointly dependent variables, and the prices of output and variable inputs and the quantities of fixed inputs are the predetermined variables of the model. An alternative set of five jointly dependent variables consists of profits and expenditures on each of the four variable factors of production. Thus, in equations (1) and (2), the variables on the left-hand side may be regarded as the jointly dependent variables and those on the right-hand side may be regarded as the predetermined variables. It is further assumed that the matrix of independent variables is constant in repeated samples and has full rank with probability one.

As in the earlier study of Lau and Yotopoulos, we follow the usual and admittedly ad hoc practice of assuming an additive error identically distributed across farms with zero expectation and finite variance for each of the equations (1) and (2). For the same farm, the covariance of the errors of any two of the three equations is assumed to be nonzero. However, the covariance of the errors of any two equations corresponding to different farms is assumed to be identically zero.

Under these conditions, ordinary least squares applied to each of the equations (1) and (2) separately will be consistent but not necessarily efficient. Zellner's method, on the other hand, is asymptotically efficient, and it is the method used, with appropriate linear constraints imposed as necessary.

Empirical Results

To test the validity of the restrictions implied by the hypotheses of profit maximization, constant returns, and absence of structural change, test statistics based on F-ratios are used. The overall level of significance is set at 0.05. First, a level of significance of 0.01 is assigned to the test of the equality restriction implied by profit maximization in 1967 and in 1968, respectively. Then, a level of significance of 0.03 is assigned to the tests on the structure of the technology, that is, the test of constant returns to scale in 1967 and in 1968 and the test of structural change, all conditional on the validity of the hypothesis of profit maximization. Because these two sets of tests are "nested," under the null hypothesis the sum of levels of significance of the two sets of tests provides a close approximation to the level of significance for both sets of tests simultaneously. (For a discussion of "nested" hypotheses, see Scheffé; for a discussion of simultaneous statistical inference, see Miller.) A level of significance of 0.01 is assigned to each of the three hypotheses of constant returns in 1967, constant returns in 1968, and structural change.

The first hypothesis to be tested is that of profit maximization: H_0: $\alpha_i^{*\Pi} = \alpha_i^{*i}$, $i = L, A, M, F,$

[2] The Chow test is not directly applicable because there are five stochastic equations in each period and the errors are not assumed to be homoscedastic.

Table 1. *F*-Ratios for Tests of Profit Maximization and Constant Returns to Scale, 1967 and 1968

Degrees of Freedom		Equality*	Constant Returns to Scale Conditional on Equality*	Critical Values of *F*-Ratios Levels of Significance 0.01	0.05
Year 1967	(4,177)	2.075		3.42	2.42
	(1,181)		0.302	6.77	3.90
Year 1968	(4,182)	1.790		3.42	2.42
	(1,186)		0.712	6.77	3.90

* Restrictions are defined in text.

separately for 1967 and 1968, where the superscript denotes the equation from which the parameter is estimated. Conditional on the validity of the equality hypothesis, the hypothesis of constant returns to scale is tested separately for 1967 and 1968: H_0: $\beta^*_K + \beta^*_T = 1$.

The test statistics are presented in table 1. At a 0.01 significance level each, the hypothesis that the restrictions implied by profit maximization are valid for 1967 and 1968 cannot be rejected. Proceeding conditionally on the validity of the hypothesis of profit maximization, the hypothesis of constant returns to scale cannot be rejected. Critical values for our test statistics for levels of significance equal to 0.01 and 0.05 are presented so that the reader can evaluate the test results for alternative allocations of the overall levels of significance among stages of the test procedure.

The parameter estimates for 1967 and 1968 are presented separately in tables 2 and 3. In the first column are the coefficients estimated from ordinary least squares. In the second column, the co-

See table 2 for footnotes.

efficients estimated from Zellner's method without restrictions are given. These estimators are more efficient than the single-equation ordinary least squares estimators. Their efficiency, however, may be further improved, if one is willing to maintain the hypothesis of profit maximization and impose the corresponding restrictions. Such restricted estimates are reported in the third column. Finally, the fourth column provides coefficients estimated by Zellner's method imposing the linear constraints implied both by profit maximization and constant returns to scale.

Next, we test whether parameters of the normalized restricted profit function are the same in 1967 and in 1968. This test is of interest not so much because of the possibility of technical progress, inasmuch as the two years are consecutive, but because the test may indicate the degree of stability of the parameter estimates.

To test the validity of the hypothesis of absence of structural change, test statistics are derived in a manner similar to that of the Chow test. The principal difference between these test statistics and the Chow test lies in the fact that the former generalize the Chow test to the case in which there is more than one stochastic equation and the variance-covariance matrix of the system as a whole is not homoscedastic.

Specifically, the system of equations consisting of the natural logarithm of normalized profits and the four factor-share equations may be considered as one single univariate equation with a heteroscedastic variance-covariance matrix of errors. The test of structural change is equivalent to a test of whether the coefficients estimated from such a system for 1967 is the same as those estimated for 1968. In order to put the problem into canonical form so that it is suitable for the direct application of the Chow test, both the dependent and the independent variables of the system of five equations are transformed by premultiplying by a suitable matrix P that transforms the error of the system of equations into a homoscedastic disturbance. This matrix P has the property that $P \Sigma P' = I$, $P'P = \Sigma^{-1}$, where Σ is the variance-covariance matrix of the error of a typical observation of the five-equation system. Given a consistent estimator of Σ, a consistent estimator of P, say $\hat{P}$, can be computed. Using this $\hat{P}$, one may transform the 1967 and 1968 problems into an equivalent univariate problem with a homoscedastic variance-covariance matrix. The Chow test procedure is then carried out for 1967 and 1968 with the transformed problem in a straightforward manner.

Structural change between 1967 and 1968 is tested conditional on the validity of the hypothesis

[a] Superscripts 1 and 2 of the constant refer to 1967 and 1968, respectively. Coefficients corresponding to the dummy variables are omitted for lack of space.
[b] Numbers in parentheses are estimates of asymptotic standard errors.

of profit maximization in 1967 and 1968. The test of structural change may be decomposed into three sequential stages: (*a*) no structural change in the parameters of the normalized profit function between 1967 and 1968, except for the intercept term and the dummy variables; (*b*) no structural change except for the intercept; and (*c*) no structural change. Under (*c*), the two normalized profit functions for 1967 and 1968 are identical in every respect. A level of significance of 0.0033 is allocated to each of the three stages of the test of structural change. These three tests are "nested"; thus, under the null hypothesis the sum of levels of significance of the three tests provides a close approximation to the level of significance for the three tests simultaneously. The test statistics corresponding to each of the three stages are, respectively: $F(6{,}369) = 1.693$, $F(7{,}375) = 2.004$, and $F(1{,}382) = 0.3764$. At the 0.0033 significance level, none of the three stages of hypotheses can be rejected. Thus, technology is apparently stable between 1967 and 1968.

On the basis of the test of structural change, the two cross sections of data are combined and parameters reestimated for the normalized profit function. These parameter estimates are reported in table 4. The first column reports the coefficients estimated without the equality restrictions on either the intercept or the dummy variables. The second column reports the coefficients estimated without the equality restriction on the intercept. The third column reports the coefficients estimated with all the equality restrictions imposed. The coefficients with all the equality restrictions and constant returns imposed are given in the fourth column. For the purpose of further discussion and analysis,

these final estimates are adopted, in view of our results of hypothesis testing. The coefficient estimates of the normalized profit function for 1967 and 1968 pooled satisfy the conditions of monotonicity and convexity.

Comparison with Other Studies

Using the parameter estimates of the normalized restricted-profit function reported in table 4, one may derive the indirect estimates of the production elasticities of the Cobb-Douglas production function that underlies the normalized restricted-profit function. These estimates are consistent estimates of the production-function elasticities. They are referred to as indirect estimates so as to distinguish them from the direct estimates, which are obtained by estimating the production function directly.

Both the indirect and the direct production-function elasticities for the pooled data are reported in table 5, as well as production-function elasticities obtained by other studies of Taiwan agriculture. Our indirect estimates of the production elasticities are not strictly comparable to the directly estimated production elasticities. The former estimates are consistent and asymptotically efficient given the stochastic assumptions. The latter estimates are generally inconsistent because of the existence of simultaneous equation bias. In addition, the estimates obtained from other studies may also be different because of differences in the type of data (cross section or times series), the time period, the type of output, and the degree of disaggregation of the inputs.

The differences among the alternative direct estimates are striking, as are the differences between our indirect estimates and direct estimates of the same parameters. The land elasticity obtained from our direct estimation of the production function appears to be too low. The labor elasticity also appears to be low in view of the significant labor share (40%) in total cost. We attribute these biases in the directly estimated elasticities to the existence of simultaneous equations bias in the direct estimation of the production function. However, in a model with five stochastic equations, it is difficult to isolate a priori the precise cause of the direction and magnitude of these biases.

Our indirect estimates are consistent with the a priori expectations of economic theory. They indicate that labor and land are by far the two most important factor inputs. Fertilizer is next in importance with an elasticity of approximately 0.10. Animal and mechanical labor inputs do not figure prominently in 1967 and 1968. Fixed assets also has a low elasticity. These findings are consistent with the observation that while Taiwan agriculture has undergone substantial technological progress in the past quarter of a century, most of the innovations have been of the labor-using type. Thus, labor remains the most important variable input of production.

Conclusions

Using the estimates from the fourth column of table 4, one can compute the output supply and factor demand own- and cross-price elasticities as well as elasticities with respect to the fixed factors of production. These elasticities are presented in table 6. The own-price elasticities of output and variable inputs are all greater than one in absolute value, indicating an elastic response of factor utilization. The cross-price elasticities, on the other hand, are rather low, with the exception of the price of output and the price of labor. The cross-price elasticities

Table 6. Own- and Cross-Price Elasticities and Elasticities with Respect to the Fixed Inputs, 1967 and 1968 Pooled

	P_A	q_L	q_A	q_M	q_F	Y_K	Y_T
V_S	1.2477	−0.9798	−0.0356	−0.0017	−0.2306	0.0702	0.9298
X_L	2.2477	−1.9798	−0.0356	−0.0017	−0.2306	0.0702	0.9298
X_A	2.2477	−0.9798	−1.0356	−0.0017	−0.2306	0.0702	0.9298
X_M	2.2477	−0.9798	−0.0356	−1.0017	−0.2306	0.0702	0.9298
X_F	2.2477	−0.9798	−0.0356	−0.0017	−1.2306	0.0702	0.9298

between the variable inputs are all negative, indicating that all the variable inputs are more complements than substitutes. The output supply and factor demands appear to be quite sensitive to changes in output price.

The elasticities of output supply and factor demands with respect to the fixed factors of production show that there is almost unitary elasticity with respect to land. On the other hand, the elasticities with respect to fixed assets appear to be negligible. These elasticities with respect to the fixed inputs measure the response of price-taking profit-maximizing farms with respect to an exogenous change in the fixed factors, holding the prices of output and variable inputs constant. Thus, they reflect the *mutatis mutandis* effect of a change in the quantity of a fixed input, allowing the farm to adjust its output and variable inputs optimally and are not comparable with the production function elasticities, which reflect the *ceteris paribus* effect of a change in the quantity of a fixed input, holding the quantities of the variable inputs constant. The *mutatis mutandis* effect is much greater than the *ceteris paribus* effect, as expected. For purposes of prediction and policy analysis, frequently it is the *mutatis mutandis* elasticity that is relevant.

This paper extends an earlier study done by Lau and Yotopoulos. It is found that the hypothesis of profit maximization cannot be rejected. Thus, the agricultural households in Taiwan may therefore be regarded as efficient producers at least within their own environment.[3] Moreover, it appears that even in situations in which the direct production-function estimation yields unreasonable estimates, as is in the present case, the normalized profit function and factor demand functions approach gives reasonable estimates for the parameters of the production function.[4] Hence, perhaps this approach should be given more weight in the empirical analysis of production using data from nonexperimental situations.

[Received July 1975; revision accepted January 1976.]

[3] In retrospect, as a referee pointed out, a substantially higher level of significance for the entire sequence of tests could have been used without rejecting any of the null hypotheses. This higher level of significance, being associated with greater power for rejection, lends additional support for the validity of the final model used.

[4] In a parallel study of Thailand agriculture, Adulavidhaya, Kuroda, Lau, and Yotopoulos also find that the normalized restricted profit function approach gives reasonable estimates of the production function elasticities, whereas the direct estimation of the production function gives unreasonable estimates.

The Demand for Agricultural Commodities in Ghana: An Application of Nonlinear Two-Stage Least Squares with Prior Information

Walter Haessel

Very little is known about the price responsiveness of either Ghanaian consumers or agricultural producers (see Agbetsiafa, Bateman, and Haessel and Appiah). This paper reports on some attempts to estimate price and income elasticities of demand for some of the major staples consumed in Ghana. Prior information on the income elasticities was incorporated using the mixed estimation procedure outlined by Theil and Goldberger. The method of incorporating the prior information resulted in a nonlinear estimation problem.

The underlying economic model and related statistical methodology are outlined in the following section. This is followed by a brief discussion of the data and a presentation of the results. The paper concludes with an investigation of the relative importance of price and income elasticities in projecting demand for foodstuffs.

Method of Analysis

The quantity of any commodity consumed in any period is assumed equal to total domestic production plus net imports. The quantity of a particular commodity produced in any one season depends on the acreage planted in the previous planting season, the yield of the commodity, and the intensity with which it is harvested. The acreage planted does not depend on the price at harvest time but rather on the price expected at harvest. To the extent that yield depends on husbandry, and husbandry and harvesting intensities in turn depend on current price, current production will depend on current price. However, it is assumed that these latter two influences are relatively unimportant and production of each commodity is assumed to be predetermined.

With the exception of rice, Ghanaian net imports of the commodities considered in this study are negligible and amount to less than 1% of domestic production. For rice, however, imports were relatively large throughout the sample period and in some years exceeded domestic production. Consequently, the domestic price of rice is determined by the import price and the quantity imported is determined by excess demand. For the remaining commodities, however, prices must adjust to clear the market since availability per capita is essentially predetermined by planting decisions in the previous year.

The quantity of a particular commodity demanded by an individual consumer depends on the commodity's own price, the prices of substitutes and complements, and the consumer's income. Assuming a log-linear form for the demand equations,

$$(1) \quad q_{ti} = a_{i0} + \sum_{j=1}^{n} a_{ij}p_{tj} + e_i y_t + u_{ti},$$
$$i = 1, \ldots, n, \text{and } t = 1, \ldots, T,$$

where q_{ti} is the natural logarithm of the quantity of commodity i consumed per capita,[1] p_{tj} is the logarithm of the price per unit of commodity j, y_t is the logarithm of per capita income, u_{ti} is a statistical error term, and the a_{ij}'s and e_i's are parameters (elasticities) to be estimated. The t subscripts refer to the time period. Specifically, $q_{ti} = \ln[(S_{ti} + M_{ti})/N_t]$, where S_{ti} and M_{ti} are domestic production and net imports of commodity i, respectively, and N_t is population. Based on the above discussion, q_{ti} is predetermined for every commodity except rice, which is endogenous. However, the price of rice is exogenous and all $n - 1$ remaining prices are endogenous. Per capita income is exogenous.

Let commodity n be rice. For each of the i equations other than rice there are $n - 1$ included

Walter Haessel is with the Department of Economics at the University of Western Ontario, London, Canada.

Comments by A. G. Blomqvist, R. A. L. Carter, and W. G. Tomek on earlier drafts of this paper are gratefully acknowledged.

[1] Demand equations should always be estimated on a per capita basis from time-series data. Consider an economy where prices and incomes per capita remain unchanged but total population is changing. In the absence of changes in income distribution and changes in tastes and preferences, there is no reason to expect per capita consumption to change. Thus, we have the relationship between aggregate and per capita consumption of $Q = Nq$ and $dQ = qdN + Ndq$, where N is population and Q and q denote aggregate and per capita consumption. In the above case, $dq = 0$ and $dQ = qdN$. Suppose that the demand equation is specified in aggregate form as $Q = f(P, Y)$, where P is the price of the commodity, $Y = Ny$ is aggregate income, and y is income per capita. Then $dQ = f_P dP + f_Y(Ndy + ydN)$, where the subscripts denote partial derivatives. Under the above assumptions of $dP = dy = 0$, we expect $yf_y = q$. The way to ensure this is to estimate the demand equation on a per capita basis.

[2] Meinken, Rojko, and King reached a similar conclusion for a slightly simpler case in which all the quantities were considered predetermined.

endogenous variables (the prices) and $n - 2$ excluded exogenous variables (all excluded quantities except rice). The rice equation includes n endogenous variables (the quantity of rice and $n - 1$ prices), and $n - 1$ predetermined quantities are excluded. Thus, each of the equations is just identified since the number of excluded predetermined variables is just equal to one less than the number of included endogenous variables.[2] Hence, identical estimates could be obtained by indirect least squares (ILS) and 2SLS. Both methods were applied, but only the 2SLS results are reported since the approach turns out to be simpler.[3] This is especially true in view of the prior estimate of the income elasticity (e_i) that was available from a cross-sectional study. This prior estimate was combined with the time-series sample data using the Theil-Goldberger mixed estimation technique.[4]

Equation (1) is rewritten for all T observations on commodity i in matrix form as

$$(2) \qquad Q_i = PA_i + Ye_i + U_i,$$

where $Q_i = [q_{1i}, q_{2i}, \ldots, q_{Ti}]'$, $Y = [y_1, y_2, \ldots, y_T]'$, and $U_i = [u_{1i}, u_{2i}, \ldots, u_{Ti}]'$ are $T \times 1$ vectors of variables and error terms; $P = [\iota, P_1, P_2, \ldots, P_n]$ is a $T \times (n + 1)$ matrix consisting of a $T \times 1$ column of 1's (ι) and n column vectors of prices $P_j = [p_{1j}, p_{2j}, \ldots, p_{Tj}]'$ of dimension $T \times 1$; $A_i = [a_{i0}, a_{i1}, \ldots, a_{in}]'$ is an $(n + 1) \times 1$ vector of price elasticity coefficients to be estimated; and e_i is an income elasticity coefficient to be estimated.

Let e^*_i denote the prior point estimate of e_i. The variance of e^*_i was unknown, but since it is believed that e_i should not be negative, a variance was chosen so that $\sigma_{e^*_i} = e^*_i/k$. Three alternative values for k were used: 1.29, 1.645, and 2. These correspond to values such that for a normal distribution, an interval of $\pm k\sigma$ about the mean contains approximately 80%, 90%, and 95% of the observations, respectively.

The prior information for the rice equation can be incorporated by estimating an equation of the form

$$(3) \qquad \begin{bmatrix} Q_n \\ e^*_n \end{bmatrix} = \begin{bmatrix} P \\ 0 \end{bmatrix} A_n + \begin{bmatrix} Y \\ 1 \end{bmatrix} e_n + \begin{bmatrix} u_n \\ v_n \end{bmatrix},$$

where 0 is a $1 \times (n + 1)$ row vector of 0's and v_n is an error term such that $e^*_n - e_n = v_n$, $Ev_n = 0$, and $Ev_n^2 = \sigma_{e^*_n}^2$. Equation (3) was estimated by generalized 2SLS under the assumption that u_n and v_n are independent but have different variances.[5]

Obtaining estimates of equations other than rice is slightly more complicated since the left-hand-side variables are exogenous. These equations are rewritten in price-dependent form as

$$(4) \qquad P_i = X_i\alpha_i + Y\delta_i + \epsilon_i,$$

where

$$X_i = \begin{bmatrix} 1 & p_{11} & \cdots & p_{1,i-1} & q_{1i} & p_{1,i+1} & \cdots & p_{1n} \\ 1 & p_{21} & \cdots & p_{2,i-1} & q_{2i} & p_{2,i+1} & \cdots & p_{2n} \\ \vdots & \vdots & & \vdots & \vdots & \vdots & & \vdots \\ 1 & p_{T1} & \cdots & p_{T,i-1} & q_{Ti} & p_{T,i+1} & \cdots & p_{Tn} \end{bmatrix}$$

is a $T \times (n + 1)$ matrix, $\alpha_i = (-1/a_{ii})[a_{i0}, a_{i1}, \ldots, a_{i,i-1}, -1, a_{i,i+1}, \ldots, a_{i,n}]'$ is an $(n + 1) \times 1$ column vector of parameters, $\epsilon_i = -(1/a_{ii})u_i$ is a $T \times 1$ vector of disturbances, $\delta_i = -e_i/a_{ii}$ is a scalar, and P_i and Y are as defined above. The parameters in α_i and δ_i are nonlinear combinations of the parameters of equation (1). The prior estimate of e_i was incorporated by estimating an equation of the form

$$(5) \qquad \begin{bmatrix} P_i \\ e^*_i \end{bmatrix} = \begin{bmatrix} X_i \\ 0_1 \end{bmatrix} \alpha_i + \begin{bmatrix} Y \\ 0_2 \end{bmatrix} \delta_i + \begin{bmatrix} 0_3 \\ 1 \end{bmatrix} e_i + \begin{bmatrix} \epsilon_i \\ v_i \end{bmatrix},$$

where 0_1, 0_2, and 0_3 are zero vectors of dimension $1 \times (n + 1)$, 1×1, and $T \times 1$, respectively. This equation must be estimated in terms of the original parameters (a_{ij}'s and e_i) rather than in terms of the α_i and δ_i. This was done by using Amemiya's nonlinear 2SLS procedure.[6] Since the model is linear in the endogenous variables but nonlinear in the parameters, the NL-2SLS estimates will have the same asymptotic efficiency properties as 2SLS in the linear case.

By utilizing the residuals from estimates of equations (3) and (5), it is possible to obtain estimates of the contemporaneous covariances among the equations in a manner identical to that used in obtaining the contemporaneous covariance matrix in 3SLS. This estimate of the covariance matrix can then be used to estimate all n equations as a simultaneous system and the resulting estimates will be nonlinear 3SLS. (The iterative procedure used was similar to that outlined by Gallant.)

Data

Consistent sets of data on net imports, prices, and production from 1953 to 1970 are available for rice, maize, sorghum, millet, cassava, yams, and cocoyams. To reduce the number of variables, sor-

[3] In the Meinken case, ILS is easier to apply than in the present case, since the relationship between the reduced form and the structural equations is much simpler.

[4] The advantage of using a mixed estimation procedure over assuming an exact constraint is that the former method utilizes information from both the sample and the prior estimate, whereas the latter uses only the prior information and completely ignores the information in the sample. The latter procedure is appropriate only if it is known with certainty that the prior estimate is correct. In other words, the variance of the prior is 0, which is a special case of mixed estimation.

[5] This was done by multiplying the last row of equation (3) by $\hat{\sigma}_n/\sigma_{e^*_n}$, where $\hat{\sigma}_n$ is an estimate of the standard deviation of u_n obtained from residuals of 2SLS estimates of equation (2).

[6] The heteroscedasticity problem was solved in the same way as for equation (3).

ghum was aggregated with millet (henceforth referred to as millet) and yams and cocoyams were combined (henceforth yams) since these commodities are fairly close substitutes. This left a total of five commodities. For purposes of estimation, it was found advantageous to combine yams with cassava (roots) and millet with maize (cereals).

One data problem relates to the accuracy of the quantity data. Data on production are very difficult to collect, and the methods used suggest that the production figures are probably measured with error. Furthermore, if inventories carried over from one period to the next vary substantially over time, an error in variables problem is introduced. However, given the lack of storage facilities in Ghana and the problem of storing commodities for extended periods of time in tropical climates, the carry-over stocks will be negligible and this should not be a serious problem.

The only price data available for foodstuffs in Ghana for any reasonably long period of time are wholesale prices. In estimating demand equations, retail rather than wholesale prices should be used. The consequence of using wholesale prices was investigated using wholesale and retail price indexes for locally produced foodstuffs. The evidence indicated that the elasticity of retail prices with respect to wholesale prices is 1. If this is true for individual commodities, then the retail and wholesale price elasticities of demand would be identical.

Perhaps the most crucial datum of the entire study is the expenditure elasticity for starches estimated by Ord on the basis of a cross-sectional household expenditure survey. This value of 0.78 (estimated for starches as a group and published without its standard error being given) was used as the prior estimate of the income elasticity (e^*_i) of each of the commodities. This estimate is consistent with expenditure elasticities reported by Kaneda and Johnson for three urban areas in Ghana.

Results

Three assumptions were utilized regarding the certainty of the prior information. Since the resulting estimates were all quite similar, only the estimates that gave the least weight to the prior information are reported (i.e., $k = 1.29$).

The NL-3SLS procedure failed to converge for the five commodity equations. The resulting NL-2SLS estimates are reported in part A of table 1. The estimates of the income elasticity are all positive and remarkably close to the prior estimate of 0.78 in all cases except yams. The sign of the own-price elasticity is negative in every case with the exception of that for millet. The own-price elasticity of maize seems larger in absolute value than might be expected on a priori grounds. Thus, maize and millet were aggregated into a single commodity (cereals) and the system was reestimated.

The resulting four-commodity equations are reported in part B of table 1 and conform to a priori expectations with respect to negative own-price elasticities and positive income elasticities. The NL-3SLS procedure was applied to the four-commodity case but, once again, it failed to converge. Thus, the size of the problem was reduced further by aggregating cassava and yams to form a new commodity called roots. In this case, the NL-3SLS procedure converged and the resulting estimates are reported in part C of table 1. The results conform with a priori expectations regarding signs of direct price and income elasticities. The estimates of the income elasticities differ more from 0.78 for the three-commodity estimates than for the four- and five-commodity estimates. This may be due to the fact that since fewer parameters are being estimated relative to the number of observations, the sample information has relatively more weight.

In summary, the foregoing estimates suggest that consumers in Ghana are indeed very price responsive. The direct-price elasticities, which tended on the whole to be better estimated than the cross-price elasticities (in the sense of being larger in relation to their standard errors), all exceed 1 in absolute value with the exception of cassava in the four-commodity regressions.

Agricultural Commodity Projections

The usual method of projecting demand for agricultural commodities consists of using income (or expenditure) elasticities and extrapolating on the basis of some rate of growth of income per capita and population. Prices are usually assumed to remain constant and their effects on consumption are ignored (see Ord, for example). The relatively large price elasticities found in this study suggest this could result in substantial errors if there are any changes in the relative prices of the various food commodities. Ignoring the error term, taking the total differential of equation (1), and rearranging yields

$$(6) \qquad D^*_i = \sum_{j=1}^{n} a_{ij} p^*_j + e_i y^* + N^*,$$

where D^*_i, p^*_j, y^*, and N^* indicate percentage changes in aggregate consumption, prices, per capita income, and population, respectively. If all prices change by the same percentage p^*, then equation (6) simplifies to

$$(7) \qquad D^*_i = p^* \sum_{j=1}^{n} a_{ij} + e_i y^* + N^*.$$

Projected annual percentage rates of growth of demand are presented in table 2 on the basis of the NL-3SLS three-commodity estimates for assumptions for y^* of 0.5% and 1.0% per annum and rates

Table 1. Estimated Demand Equations

A. Five-Commodity Equations	Variable						
	Intercept	Price Maize	Price Millet	Price Cassava	Price Yams	Price Rice	Income

* Standard errors of the coefficients are given in parentheses.

of change of prices of −1%, 0, and 1% per annum. The population growth rate is assumed to be 2.4% per annum.[7] The figures suggest that projecting commodity demands on the basis of changes in per capita income and population alone can result in serious errors if, in fact, the prices of the commodities in question change relative to the general price level.

Conclusions

The price elasticities estimated are fairly large in absolute value. This may, in part, be due to the poor quality of the data resulting in biased estimates. Using wholesale prices rather than retail prices may also introduce biases, although tests of this proposition indicated this was not the case.

The tentative conclusion based on the above evidence is that Ghanaian consumers respond significantly and substantially to changes in the prices of local foodstuffs. This is consistent with the limited information available on the price responsiveness in demand in other developing countries (see Alamgir and Berlage; Bussink; de Janvry, Bieri, and Nuñez; and Haessel). This demonstrates the importance of considering possible price changes in the planning process and emphasizes the importance of price policy in the agricultural sector. This is especially true when the growing evidence on demand responsiveness is combined with the well-documented supply responsiveness of agricultural

[7] This was the rate of growth of population in Ghana between the 1960 and 1970 census.

Impact of New Agricultural Technology on Farm Income Distribution in West Godavari District, India

V. T. Raju

In selected regions, Indian agriculture has experienced a substantial impact of science and "new technology" during the past decade. In recent years, a major focus has been the question of equity in the distribution of benefits accruing to individual farmers from development programs embracing new technology. The introduction of new technology in agriculture has many short- and long-run implications for the economy in general and for the farm sector in particular. One of the short-run effects is an increase in the incomes of those farmers who adopt new inputs and techniques. But the important aspect is the effect of adoption on the pattern of income distribution among farmers. The precise nature and exact magnitude of this effect is still unknown. This lack of knowledge is important in that it is now increasingly felt that the real farm problem lies not only in the low average incomes in agriculture but also in their unequal distribution among farmers.

This study attempts to measure the farm income inequality in the West Godavari district for the years 1967–68 and 1970–71 and to isolate and measure the net influence of new farm technology on the farm income distribution in the district.[1] The study is restricted to an analysis of the distributional effects of new technology on farm incomes. It does not address the question of factoral distribution effects or distribution effects among consumers and producers. The Intensive Agricultural District Program district of West Godavari was selected because agricultural modernization in such districts has been attempted with relatively more vigor and over a comparatively longer period than in other districts.[2] The data were taken from the Benchmark and Assessment surveys of the IADP district of West Godavari conducted by the Directorate of Economics and Statistics, Ministry of Agriculture, in 1967–68 and 1970–71 (Government of India). The former was selected because it was the year when the impact of new agricultural strategy launched in 1966–67 was having its first impact, and the latter was selected as it was the latest year for which the data were available. A stratified multiple-stage random sample of 400 farmers was selected in the whole district. The district is divided into sixteen community development blocks, which will be the unit of investigation.[3] In each community development block, four to six villages were selected at random, and then in each village eight farmers were selected at random. The sample farmers were interviewed by trained research investigators during both the kharif and rabi seasons each year, and detailed information relating to their farms was obtained.[4]

Findings of Simple Comparisons of Income Distribution

The size distributions of income considered are derived from a classification of the sample farm families on the basis of annual farm income. The data reveal that the average annual income for all the farm families studied in 1967–68 was Rs. 4,079 (rupees). The average income in 1970–71 at current prices was Rs. 8,389. At constant 1967–68 prices, the average income was estimated at Rs. 5,220 (Raju, p. 101). The ordinal ranking of the size distributions is clearly brought out by an analysis presented in table 1. The ninth decile group of farm families claimed about 19% of the aggregate income in 1967–68. The share increased by about 1% in

This paper is part of the author's Ph.D. thesis. The author is grateful to I. J. Singh, who guided the research and provided many valuable comments and suggestions at various stages, and to Hans P. Binswanger, James G. Ryan, M. von Oppen, and the referees of this *Journal* for their helpful comments and suggestions.

[1] West Godavari is a prosperous agricultural coastal deltaic district of the state of Andhra Pradesh in India covering an area of 3,009 square miles. It is situated on the west bank of the Godavari river, which runs through the whole length of the district before falling into the Bay of Bengal.

[2] The Intensive Agricultural District Program (IADP), popularly known as Package Program, was launched in this district in October 1960. The program covered the entire district and involved comprehensive agricultural development in all the major crops in the district (Government of India).

[3] A community development block is the smallest comprehensive developmental unit in the Indian planning structure. Each block covers approximately 100 villages and is supposed to have a full complement of specialists dealing with all technical aspects of agricultural development, plus its own allocation of publicly supplied agricultural inputs such as chemical fertilizers, new seeds, pesticides, credit, etc.

[4] The word "kharif" is used to refer to the monsoon season generally occurring from June through September or early October. The word "rabi" is used for the dry, postmonsoon season, generally occurring from October through January.

Table 1. Relative Shares of Aggregate Income Received by Various Decile Groups of Families in 1967–68 and 1970–71 in West Godavari

	Percentage of Aggregate Income			
Decile Group	1967–68	Cumulative Percentage	1970–71	Cumulative Percentage
First 10%	0.40	0.40	0.52	0.52
Second 10%	0.94	1.34	1.10	1.62
Third 10%	1.48	2.82	1.48	3.10
Fourth 10%	2.14	4.96	2.32	5.42
Fifth 10%	3.28	8.24	3.81	9.23
Sixth 10%	4.91	13.15	5.02	14.25
Seventh 10%	7.49	20.64	8.36	22.61
Eighth 10%	11.28	31.92	13.06	35.67
Ninth 10%	18.69	50.61	19.48	55.15
Tenth 10%	49.39	100.00	44.85	100.00
All groups	100.00	—	100.00	—

1970–71. The highest decile group of farm families claimed about 49% of the aggregate income in 1967–68. Their share reduced to about 45% in 1970–71. The share of the poorest 10% of the farm families increased from 0.40% in 1967–68 to 0.52% in 1970–71.[5] It now remains to see whether the improvement in income distribution was statistically significant.

There are various measures to quantify the difference in inequality between the two distributions. The measures used for this study are: the Gini concentration ratio, the standard deviation of the logarithms of incomes, and the coefficient of variation. These three were selected because they are unaffected by equal proportional increases in all incomes and are sensitive to disproportionate changes at all levels of income. Among the three measures the standard deviation of logarithms of incomes attaches more weight to transfers affecting the lower income classes, the Gini concentration ratio attaches more weight to transfers affecting the middle income classes, and coefficient of variation attaches equal weights to transfers at different levels of income (Atkinson). The most striking feature of the data is that income inequality appears to have fallen from 1967–68 to 1970–71 in the district as a whole in terms of all the three measures (Raju, p. 107). A statistical test was made to determine whether the decline in income inequality from 1967–68 to 1970–71 is significant or not.[6] Based on that statistical test, the null hypothesis that the distribution of farm income in the district for the year 1967–68 is the same as that for the year 1970–71 is rejected at a significant level of 5%. There was a significant decrease in income inequality from 1967–68 to 1970–71 in the district.

There has also been a statistically significant increase in average per farm expenditure for new technology in the district in the period 1967–68 to 1970–71. This increase has been accompanied by a statistically significant decline in the relative variance of the per farm expenditure for new technology (Raju, p. 115). The average area under crops per farm has significantly increased, accompanied by a significant decrease in the relative variance of the cropped area.[7] The average net farm income at current and constant prices in the district recorded a statistically significant increase.[8] The increase in the mean farm income affects farm income inequality according to the position on the income distribution of those whose incomes have increased.

Analysis of the Sources of Changes in Income Inequality

The statistical model used for measuring the net influence on income distribution of selected causal factors is multiple-regression analysis. Assuming that a relationship exists between the farm income inequality Y and the explanatory variables X_1, X_2, X_3, X_4, and X_5, both linear and Cobb-Douglas regression models of the following form were fitted:

$$(1) \quad Y_i = B_0 + B_1X_{1i} + B_2X_{2i} + B_3X_{3i} + B_4X_{4i} + B_5X_{5i}$$

and

$$(2) \quad Y_i = B_0\, X_{1i}^{B_1}\, X_{2i}^{B_2}\, X_{3i}^{B_3}\, X_i^{B_4}\, X_{5i}^{B_5},$$

where Y_i is the income inequality as measured by the standard deviation of the logarithms of the incomes (Y_{1i}), the coefficient of variation (Y_{2i}), and the Gini concentration ratio (Y_{3i}) of the incomes in the ith block; B_j's are the unknown parameters to be estimated ($j = 0, 1, \ldots, 5$); X_{1i} is the relative variance (squared coefficient of variation) of per farm expenditure for improved seeds, fertilizers, plant protection chemicals, and irrigation water in the ith block; X_{2i} is the mean expenditure per farm

[5] The data in table 1 is used to draw the Lorenz curves, and the Lorenz curve of 1970–71 lies above the 1967–68 curve at all points (Raju, p. 105).

[6] F-test is used assuming that income is log-normally distributed with mean μ and variance σ^2 and $\hat{\sigma}_1^2$ and $\hat{\sigma}_2^2$ are dependent and unbiased estimators of σ_1^2 and σ_2^2, respectively. The null hypothesis H_0: $\sigma_1^2 = \sigma_2^2$ is tested against the alternative hypothesis H_1: $\sigma_1^2 \neq \sigma_2^2$, where σ_1^2 and σ_2^2 are the variances of logarithms of the 1967–68 and 1970–71 farm incomes, respectively. The calculated F-value was 1.179 and the critical F is 1.16 at the 5% level. Hence, H_0: $\sigma_1^2 = \sigma_2^2$ is rejected and H_1: $\sigma_1^2 \neq \sigma_2^2$ is accepted.

[7] The mean cropped area per farm was 13.45 acres in 1967–68, and by 1970–71 it is increased to 17.87 acres; the variance of the cropped area is decreased from 1.112 in 1967–68 to 0.955 in 1970–71 (Raju, p. 116). The increase in mean cropped area may be due to the expansion of irrigation facilities, increased use of fertilizers, and introduction of new crop rotations in the district because it has now become possible to grow two or even three crops a year on the same piece of land where only one crop was grown before.

[8] The average farm income in the district recorded a statistically significant increase of about 107% at current prices and 29% at constant prices (Raju, p. 117).

for improved seeds, fertilizers, plant protection chemicals, and irrigation water in the ith block; X_{3i} is the relative variance of the cropped area per farm in the ith block; X_{4i} is the mean cropped area per farm in the ith block; X_{5i} is the mean (log) farm family income in the ith block; and i is 1 to 16 (numbers of blocks).

Theoretically, one could think of a large number of factors that can influence income inequality. If the farm income of a member of a group of farm families is expressed as the sum of the payments to factors of production owned by the member, then income inequality within the group can be analyzed as a function of the relative shares of the factors of production and distribution of factors of production among the members of the group. Besides, any factor that affects either the relative shares of factors of production or the distribution of factors of production or both can also affect income inequality. In this study, only those factors that appear to have special significance in the context of the recent developments in the study area, that is, in the adoption of new agricultural technology such as high yielding varieties of crops, chemical fertilizers, plant protection chemicals, irrigation water, etc., the area brought under multiple cropping and the gross value of farm production are considered.

If the proposition that there is a positive relationship between the level of adoption of new technology and the level of farm income is accepted, then one could expect a similar relationship between inequality in the distribution of income from new technology and inequality in the rates of adoption of new technology.[9] Therefore, the relative variance (squared coefficient of variation) of per farm expenditure for new technology is introduced, and a positive sign for its coefficient is expected. The mean level of per farm expenditure for new technology is also introduced, but since its effect on the distribution of income depends on which group receives more, the sign is undetermined on the theoretical basis.[10] The relative variance of land holdings is expected to have a positive sign, and land holding is the main item in the assets of the farmers. Changes in the mean cropped area again can have a positive or negative effect on the inequality measures, depending on the position of the gains and losses. The mean farm income is included because the increase in the farm income may affect farm income inequality according to the position on the income distribution of those whose incomes have increased. But again, no a priori hypothesis for the sign of the coefficient of this variable can be made.

The regression models are estimated by the method of least squares. Four variants of the regression model are estimated. The first and second variants attempted to explain the block (spatial) differences in farm income inequality for the years 1967–68 and 1970–71, respectively. The third and fourth variants attempted to explain the absolute and relative changes (temporal) in income inequality from 1967–68 to 1970–71, respectively.[11]

Results of Regression Analysis

Table 2 contains the results of all the four variants of the regressions in linear form fitted to explain the spatial and temporal differences in income inequality. The results indicate that, throughout all the four variants and with the three types of dependent variables, the relative variance of the per farm expenditure for new technology (X_1) is the only explanatory variable that has a statistically significant effect on the farm income inequality. However, the level of significance varied among different variants and with different dependent variables. The coefficient obtained the expected sign throughout in all the cases. The implication of this result is that the decrease in income inequality in the district from 1967–68 to 1970–71 was due mainly to a decline in the relative variance of the per farm expenditure for the new technology over the period. This means that a more uniform pattern and level of adoption of new technology among farmers in 1970–71 led to a drop in the farm income inequality in the district. This result may be due to the fact that the period covered the closing phase of an adaption cycle in which selective adoption by early innovaters may first have caused an increase in inequality that was closed as adoption became widespread.

The coefficient of the mean expenditure for new technology (X_2) has a negative sign in most of the cases except for the regression of 1967–68 when the standard deviation of the logs of income and the coefficient of variation are dependent variables and for the 1970–71 regression with Gini concentration ratio. The coefficient is significant only for two variants, that is, absolute and relative changes when the standard deviation of logs of income is the dependent variable. As discussed earlier, the mean expenditure for new technology is expected to have a direct relationship with the income inequality. It is the differential rates of adoption of new technology as characterized by the relative variance of the per farm expenditure for new technology that is directly related to the income inequality. The nature of this indirect relationship between the mean

[9] For instance, adoption of new technology by a subset of farmers can lead to a change in farm income inequality, according to the position in the income distribution of those who adopt. If the adopters are on the lower end of the income distribution, one can expect income inequality to fall and vice versa.

[10] If an increase in the mean level of adoption is accompanied by a decline in the inequality of the rates of adoption brought out by a more than proportionate increase in the ratio of adoption by those at the lower end of the distribution, one could expect a negative coefficient for this variable.

[11] Since the aggregation of the variables included in the model was done at the block level, the total number of observations were equal to the number of blocks in the district. Thus, for each variant there were sixteen observations.

expenditure for new technology and the income inequality depends on the nature of the former's relationship with the relative variance of the per farm expenditure for new technology. Findings in table 2 support this contention because the variables X_1 and X_2 are negatively correlated both across blocks as well as over time, as indicated by zero-order correlation matrices, with X_1 having a positive sign and X_2 showing a negative sign (Raju, p. 185). The coefficient of the relative variance of the cropped area (X_3), which reflects differences in the distribution of the cropped area among the sample farms, has the expected positive sign in all the regressions. But the coefficient is never statistically significant. The coefficient of the per farm cropped area (X_4) has a negative sign and is significant in most of the cases. Finally, the mean level of income (X_5) has a negative coefficient in most of the cases and is not statistically significant in many cases. As the results of the Cobb-Douglas form are more or less similar to those of the linear, they are not presented here.

The results of this study differ with the views of some economists who argue that the stage has not been reached in Indian agriculture in which equality in the rates of adoption of new technology among operators of small and large farms and the resulting income inequality start declining. But in the IADP district of West Godavari, special arrangements for supply of new production inputs and credit and for training and education of farmers in the use of new technology did reduce the early inequality in the rates of adoption of new technology among operators of small and large farms and also the income inequality. The base year, that is, 1967–68, was the year when the impact of the new agricultural strategy launched in 1966–67 was visible on the farm front, that is, early in the adoption cycle of

high yield varieties (HYV's).[12] This changed the level of resource use, and new technology caused an upward shift in the production function, especially for paddy and wheat, thereby increasing farm incomes. Thus, the positive relationship between new technology and farm incomes that started in 1967–68 continued until 1970–71 and beyond. A similar positive relationship between reductions in inequalities in the rates of adoption of new technology and inequalities in the distribution of income from new technology also occurred. The government investment in such infrastructure facilities and other services as tube wells, fertilizers, credit, marketing, extension, and training, etc., in this district enabled all size groups of farmers to benefit from new technology. Since these facilities and services increased both in quality and quantity from 1967–68 to 1970–71, inequality in the rates of adoption of new technology between the small and the big farmers dropped and so did the farm income inequality.

Conclusions

The results of this study suggest two major conclusions. First, the estimates of income inequality indices indicate an overall decline from 1967–68 to 1970–71 in the farm income inequality in the district. Second, the more equal adoption of new farm technology has significantly reduced income inequality. Although the results of the study are based on only two separate crop years of a single district of India, which is a fairly large country, and the district is an IADP area in which the government took more interest than in other areas, the conclusions of this study may serve as a guideline for the following possible implications for policy purpose.[13] The increasing mean levels of farm income associated with the declining farm income inequality in the district over the period 1967–68 to 1970–71 represent a step towards the achievement of a higher level of economic well being for farmers. The introduction of new agricultural technology in the district led to an increase in the economic welfare of the farm people because all income groups were better off in terms of their mean incomes and no group was worse off than before. The results of this research demonstrate a possibility of simultaneously increasing the mean level of income and reducing income inequality. This is what India wants to achieve by means of various agricultural development programs and policies. This conclusion is useful for policymakers who could reduce the unequal distribution of incomes by extending the development programs and policies that are adopted in IADP areas to other areas where the income inequalities are increasing.

The increased incomes are usually associated with increased consumption of material goods and services. This could lead to a short-term conflict between the present consumption level and the investment in new technology. The conflict would be more serious with more equitable distribution of income between the higher income farmers and the lower income farmers because of the latter's higher propensity to consume. However, the increase in the average expenditure for new technology from 1967–68 to 1970–71, accompanied by a decline in the relative variance, seems to indicate that investment in new agricultural technology is not affected adversely. This could be due to a change in the attitude of the farmers who are now becoming increasingly conscious of the need to invest directly in productive activities even if some restraints are imposed on their current consumption. This suggests that a conflict between present consumption and investment in new technology is not inevitable in the process of agricultural development. The substantial increase in the average expenditure for new agricultural technology recorded for the lower income groups in the period 1967–68 to 1970–71 seems to suggest that there is nothing inherent in new technology that makes it suitable for higher income farmers and unsuitable for lower income farmers. This is because the main components of new technology, namely, improved seeds, fertilizers, plant protection chemicals, etc., are all perfectly divisible and could be used in any quantities. Even the services of a tractor, an irrigation pump, or some other improved farm equipment could be hired in.

[*Received August 1974; revision accepted December 1975.*]

[12] HYV's of paddy have been first introduced in this district during 1966–67 in an area of 4,210 acres. The area under HYV has increased to 73,000 acres in kharif season and 137,000 acres in rabi season during 1970–71. At present, there are as many as twenty HYV's of paddy that are being tried (West Godavari, p. 6).

[13] IADP districts are different than other areas where inputs are not evenly distributed.

A Note on Unemployment and Labor Migration in Less Developed Countries: A Diagrammatic Illustration

Ozay Mehmet

The relevance of economic theory for providing a rational explanation of the unemployment problem of LDC's has long been a topic of controversy (Schultz, Paglin, Hansen, Reynolds, Berry, Horowitz). In particular, in recent years there has been a considerable attention devoted to the perplexing fact of significant rural to urban migration in the face of large urban unemployment (Harris and Todaro).

This note presents a simple two-sector model of unemployment equilibrium in an attempt to offer an economic rationale for this curious fact. The model implies a trade-off process between disguised unemployment in the rural sector and open unemployment in the urban sector.[1] In addition, the note takes explicit and full account of the influence of seasonal fluctuations in farming activities on labor demand and wage determination and the extended family system that performs the dual functions of setting the supply price of labor in the urban sector and giving rise to a system of income maintenance that is financed significantly out of cash remittances from the urban to the rural sector. The importance of the seasonality factor has been recognized in the past (Berg, Elkan) but the role of remittances has been introduced only recently (Mehmet 1971b, Waters). Both the seasonality factor and cash remittances have to be incorporated into any comprehensive model of unemployment equilibrium purporting to explain the labor market mechanism in the LDC's.

The present model assumes a two-sector economy featuring internal trade and factor mobility. There is perfect competition with producers in both sectors behaving as profit maximizers and consumers and workers as utility maximizers. In figure 1, the right-hand quadrant depicts labor market conditions in the urban sector in which wage employment predominates, while the left-hand quadrant refers to the rural sector in which traditional subsistence farming predominates. The extended family system exists throughout the economy. OW_s is the minimum subsistence real wage rate, and it is guaranteed to each and every person within the extended family regardless of individual (marginal) contribution to family income. Therefore, OW_s acts as the minimum supply price of labor in the urban sector. Total labor endowment is equal to M_3N_1, of which OM_3 is in the rural and ON_1 in the urban sectors. Demand for labor in the two sectors are represented by D_rD_r and D_uD_u, the former reflecting off-season demand conditions.

If voluntary migration of labor from the rural to urban sector prompted by real wage differential is assumed, equilibrium conditions in the two labor markets cannot uniquely be determined because the volume of migration cannot a priori be specified. In one extreme case, all of the disguised unemployment might choose to stay in the rural sector. This might happen if the income support system of the extended family is so comprehensive that it effectively defeats incentive and desire for wage employment and economic independence. In the opposite extreme case, all of the disguised unemployed might move to the urban sector in anticipation of higher real income. In the former case, disguised unemployment would equal M_1M_3, with M_1M_2 having marginal product equaling 0 or more (but less than OW_s) and M_2M_3 having negative marginal product. OM_1 amount of labor would be employed receiving minimum subsistence real wages. The corresponding equilibrium in the urban sector would feature ON_1 employment at a real wage rate of OW_1. If we assume the possibility of cash remittances from the urban to the rural sector, channeled through the extended family system, an amount of real income up to $ON_1 \cdot W_sW_1$ might be transmitted to support the disguised unemployed. Whether or not such income transfers would be adequate to raise the average per capita real income in the rural sector to OW_s would depend on the volume of disguised unemployed initially and the slope of the D_uD_u curve. Under normal conditions,

[1] Disguised unemployment here is defined in the sense of the marginal product being less than the subsistence real wage rate. This definition implies that disguised unemployment consists of two parts, one characterized by negative marginal product and the other characterized by a marginal product equal to or greater than 0 but less than the subsistence real wage rate. This is illustrated in figure 1, in which the first type of disguised unemployment is represented by M_2M_3 and the second by M_1M_2. The present definition tends to overcome the identification problem of whether or not disguised unemployment necessarily implies zero or negative marginal product of labor—a topic of long controversy (Mehmet 1971a).

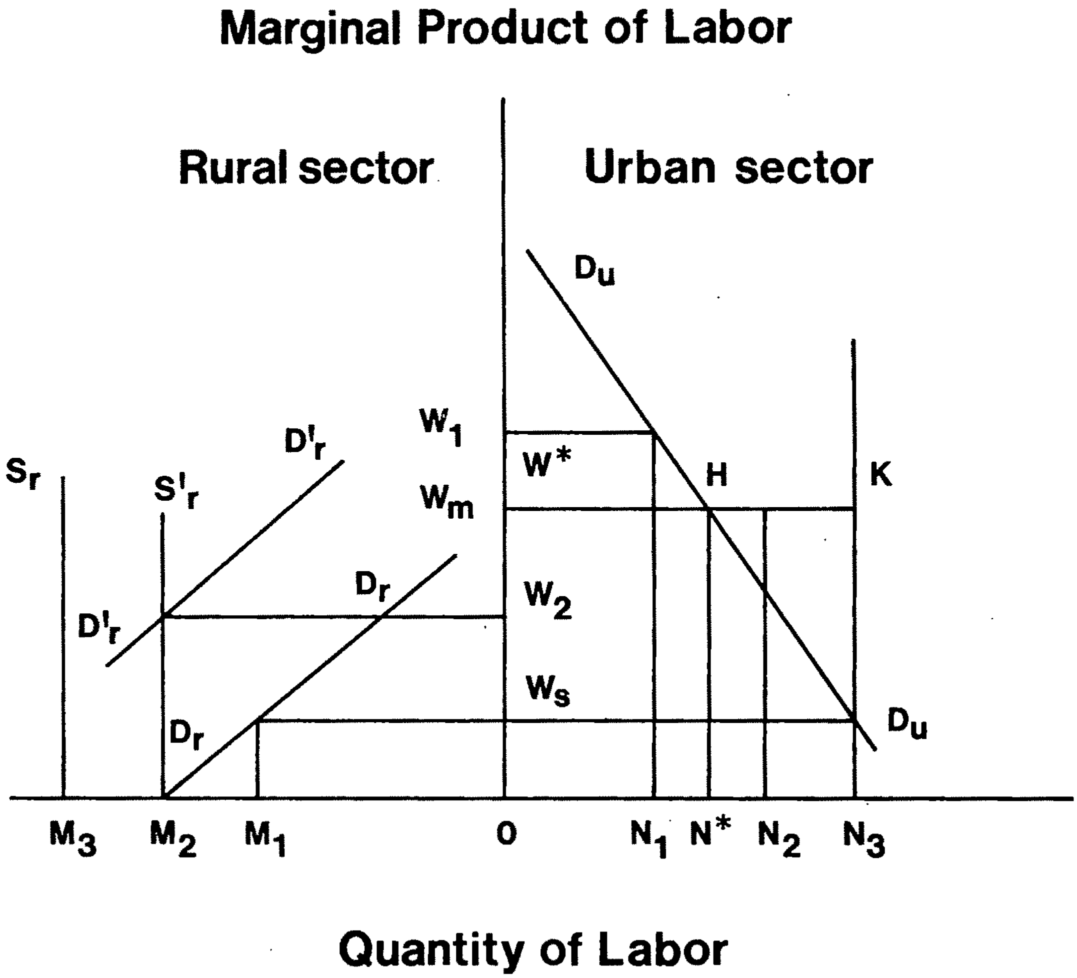

Figure 1. Real wage rate for the two-sector economy

it may be assumed in fact that the average per capita real income is capable of being raised to OW_s.

Given the assumption of rational migration, some of the disguised unemployed would be motivated to move to the urban sector in search of wage employment. So long as the real wage rate offered to them is no less than OW_s, they would be better off by accepting such employment. The limiting case is when all of the disguised unemployed move to the urban sector and a common real wage rate equaling the subsistence wage is established throughout the economy.[2] Thus, if no minimum urban wage rate existed, equilibrium in the urban labor market could be established anywhere between the limits of OW_s and OW_1. Within this range, there would be wage flexibility.

[2] It is assumed that the overall population is not excessive relative to aggregate supply of cooperant resources. If overpopulation existed in this sense, then one could expect strong "push" effects causing international migration or its elimination in the long run through sheer starvation.

Suppose, however, that an urban minimum wage rate, denoted by OW_m in figure 1, is introduced either for political reasons and/or trade-union demands. This would reduce the range of wage flexibility to the distance between W_m and W_1 and thereby effectively preclude the establishment of a common real wage rate OW_s in the extreme case described in the preceding paragraph. The minimum urban wage rate OW_m would create a horizontal supply curve and would be capable of generating excess supply up to a maximum of HK. This maximum is determined by the initial quantity of disguised unemployment in the rural sector, M_1M_3, and reflects the situation in which all of the disguised unemployed migrated to the urban sector: N_1N^* of them would secure employment at the minimum urban wage rate OW_m, while the remainder of HK would become unemployed. Given the minimum urban wage rate OW_m, the only way to achieve a full-employment equilibrium in the urban sector would be to tolerate disguised unemployment in the rural sector. Thus, there is a trade-off

between urban and disguised unemployment underlying the model depicted in figure 1: any equilibrium would entail some type of unemployment such as disguised, urban, or a combination of both. If the minimum urban wage rate were eliminated, wage flexibility could bring about a common wage rate at OW_s ensuring bare subsistence for everyone with OM_1 amount of labor allocated to the rural and ON_3 to the urban sectors. Once wage inflexibility is introduced, some form of unemployment is inevitable. Since the extended family system is assumed to exist throughout the economy, the unemployed would be supported by their employed relations.

The unemployment equilibrium described above is unlikely to persist for any significant length of time because of a unique characteristic of the rural sector, namely, seasonal fluctuations in farming activities associated with planting and harvesting crops during peak seasons followed by periods of slack during off-seasons. Suppose that, immediately prior to the onset of a peak-season, labor allocation between the two sectors is such that there is OM_2 amount of labor in the rural sector, with M_1M_2 volume of disguised unemployed. Then there is ON_2 amount of labor in the urban sector, with N^*N_2 volume of urban unemployment.[3] Suppose, moreover, that the onset of the peak season shifts the demand curve in the rural labor market from D_rD_r to $D_r'D_r'$ *ceteris paribus*. With only OM_2 amount of labor in the rural sector, increased demand would raise the real wage rate from OW_s to OW_2. All the disguised unemployed would now be absorbed in productive employment receiving wages significantly above subsistence level. If it is assumed that part of these additional earnings are reserved for use during the slack season to supplement financial assistance provided out of extended family sources, then one would have a rational explanation for the persistence of disguised unemployment in LDC's based on the seasonality factor coupled with the extended family system.

Indeed, the seasonality factor would offer a rationale for the pattern of temporary labor migration observed in some LDC's. Suppose, for example, that the increase in demand for labor in the rural sector during the peak season is substantial enough to raise the wage rate to OW^* above OW_m. Consequently, all of the unemployed as well as some of the employed persons in the urban sector, acting rationally, would move back into the rural sector attracted by the relatively higher rural real wages.[4] The resulting equilibrium in the urban sector is likely to feature a volume of employment somewhat less than ON^* with a wage rate somewhat higher than OW_m, while the equilibrium in the rural sector is likely to be established at a point corresponding to a volume of employment somewhat larger than OM_2 and a wage rate somewhat less than OW^*. In general, urban-rural migration, conceivable during peak seasons, is parallel to the more usual migration in the opposite direction in that it, too, is motivated by expected higher real earnings.

Once the peak season is over, demand for labor in the rural sector would fall back to D_rD_r, and the forces of change described in the preceding paragraph would operate in reverse direction. This whole process of change and reaction can be expected to be repeated with every seasonal change in the rural sector except, of course, in the event of bad harvests or political instability or other exceptional conditions.

Before drawing any implications from the present analysis for economic policy and planning in LDC's, it is necessary to observe its underlying limitations. There are a number of restrictive assumptions, especially regarding the existence of perfect competition in the two sectors and rational labor mobility between them. In fact, actual conditions in many LDC's are characterized by serious imperfections and rigidities (such as insufficient information about job opportunities, traditional land tenure systems, and cultural values) that adversely affect the pursuit of profit-utility maximization.[5]

Nevertheless, while the marginal conditions of the perfect competition model may not precisely conform to the real world of LDC's, there is growing empirical evidence supporting the view that the rationality principle of the price-market theory is relevant. For example, it is now increasingly being recognized that the smallholder farmer is an efficient economic decisionmaker within the bounds of the scarce resources at his disposal and the uncertainties of his environment and that he will respond positively to take advantage of profitable opportunities (Krishna, Castello, Cohen). Careful studies of the social, institutional, and cultural factors and their impact on the motivations and behavior of traditional farmers in many LDC's are now demonstrating that the alleged resistance of smallholder farmers to innovation is often due to the failure of extension workers and agricultural administrators to offer feasible, low-cost technology that promises satisfactory returns at acceptable levels of risk (Mellor; Johnston, Page, and Warr). Thus, the critical constraints on production appear to be the availability of low-cost agricultural credit to expand the working capital and technical assis-

[3] This is one of the infinitely possible sectorial allocations that can be achieved consistent with the minimum urban wage rate and supply-demand conditions as illustrated in figure 1. OM_2 amount of labor in the rural sector implies that all disguised unemployed initially with negative marginal products (i.e., M_2M_3) migrate to the urban sector where N_1N^* obtain employment at the urban minimum wage rate while N^*N_2 remain unemployed. Recall that $M_2M_3 = N_1N_2$.

[4] This would tend to explain the phenomenon of a sharp rise in absenteeism on plantations and in urban industries during harvesting seasons in dualistic economies.

[5] The model of wage determination in figure 1 can be reformulated by assuming monopsony conditions, for example, in the urban labor market. Such a reformulation would imply that the amount of remittances to the rural sector would be reduced owing to monopoly profits realized by the employer, relative to the competitive model.

tance with regard to fertilizer use, crop cultivation, and marketing, as well as the availability of low-cost farm technology.

In the face of double-digit open unemployed in urban areas of many LDC's (Turnham), it is now timely and necessary to reexamine past development objectives and strategies. In retrospect, it is clear that the postwar policies of industrialization, based on Lewis-type dualistic models, were faulty. These models were based on the concept of draining rural surpluses into nonagricultural sectors. The results in many LDC's have been widening urban-rural disequilibria featuring mounting urban unemployment coexisting with a small, capital-intensive urban sector, typically protected by artificially high tariffs (Little, Scitovsky, and Scott).

The persistence of urban-rural wage differentials, in excess of differences in marginal productivities in the two sectors, implies continued or even increased migration flows, unless remedial policies are effectively introduced. Three potential solutions have been offered. One is the reduction of urban wages by direct government action, but this is unlikely on political grounds (Berry, Smith). The second is the physical control of migration through pass system or labor laws now existing in South Africa and a few other African countries, but this, too, is unlikely to succeed owing to the repressive consequences of the proposal (Harris and Todaro). The third and most promising solution is agricultural and rural development. This is the principal conclusion of the present analysis.

In future planning and policy formulations, agrarian and rural development must be accorded much higher priority. This would be justified on grounds of both greater economic efficiency and equity. Switching development funds into the rural sector is likely to serve the multiple objectives of greater food production, more productive utilization of labor and nonlabor resources, and wider diffusion of the benefit of economic growth across the entire country instead of limiting them to urban sectors, as well as reducing the incentive for rural-urban migration.

Effects of Tax Depreciation Policy and Investment Incentives on Optimal Equipment Replacement Decisions: Comment

Ronald D. Kay and Edward Rister

The recent article by Chisholm in this *Journal* is a welcome addition to the literature on farm-asset replacement. The effect of income taxes on asset replacement has been largely ignored in the economic analyses of decisionmaking by the farm firm. Yet farmers obviously operate in an environment in which income taxes are an important factor in many of the decisions they make.

Chisholm reported the results of changes in Australian income tax legislation on the optimal replacement time for a capital asset. He also reported that, by applying U.S. income tax regulations to his data, he found an eleven-year optimal replacement policy that was the upper limit on his data. The only exception was for an after-tax discount rate of zero when the indicated replacement age was eight years. These results were reported as being unaffected by the depreciation method used or by including additional first-year depreciation and investment credit in his model.

Chisholm's results were surprising and appear to contradict the replacement patterns followed by U.S. farmers. Many full-time, commercial farmers replace their primary tillage tractors and harvesting equipment well before eleven years. The purpose of this comment is to extend Chisholm's work to another set of data under U.S. income tax regulations and to explore some reasons for the differences in optimal replacement age from that observed on many U.S. farms.

Following Perrin's suggestion (p. 65) that calculating present values for each possible replacement year may be a better procedure than evaluating the marginal criterion, the following model was used assuming all expenses, income tax, and replacement occur at year-end:[1]

$$PV_n = \frac{1}{1-(1+r)^{-n}}\Big\{(C_0 - C_n[1+r]^{-n}) + (1-T)\Big(\sum_{k=1}^{n} R_k[1+r]^{-k}\Big) - T(A_n[1+r]^{-1}) - T\Big(\sum_{k=1}^{n} D_k[1+r]^{-k}\Big) - I_n(1+r)^{-1}\Big\},$$

where PV_n = the present value (cost) of a perpetual replacement policy of n years, r = after-tax discount rate, C_0 = initial cost, C_n = market value at the end of year n in constant dollars, T = income tax rate, R_k = repair cost in year k in constant dollars, A_n = additional first year depreciation that can be taken with a replacement policy of n years, D_k = regular depreciation in year k, and I_n = investment credit that can be taken with a replacement policy of n years. For convenience, the model assumes market value and replacement age are correctly anticipated so terms for recapture of depreciation and investment credit are not needed. The replacement policy that minimizes PV_n is selected as being optimal.

Data for market value and annual repair cost were generated for a wheeled tractor with a new cost of \$15,000. The market value at the end of each year as a percentage of original new cost was estimated from the equation $RV = 65.6 - 4.1X$ using data from a study by Peacock and Brake (p. 5), where X is the tractor's age. Annual repair costs for an assumed constant 800-hour annual use were calculated from a repair cost function developed by Bowers (p. 32). Table 1 shows the year-end market value and annual repair costs in constant dollars for fourteen years.[2]

The results of this analysis are shown in table 2 for selected combinations of after-tax discount rates and tax rates. Several conclusions can be drawn from these results: (*a*) the after-tax discount

Technical Article No. 11951 of the Texas Agricultural Experiment Station.

[1] In the computer program written to evaluate the present values, additional first-year depreciation was not permitted until a six-year or longer replacement period was being evaluated and the reduced investment credit tax for a three- to six-year useful life was also included in the program.

[2] If the used machinery market was perfectly competitive, the market value of a used machine would be the net present value of its future earnings. This would cause a decisionmaker to be indifferent towards replacement ages except for the age at which the machine was scrapped. This study follows Chisholm's procedure of conducting a partial equilibrium analysis assuming constant market prices for used tractors.

Table 1. Market Value and Repair Cost Data for $15,000 Tractor

Year	End-of-Year Market Value	Annual Repair Costs
0	$15,000	$ 0
1	9,225	310
2	8,610	566
3	7,995	734
4	7,380	869
5	6,765	985
6	6,150	1,090
7	5,535	1,184
8	4,920	1,273
9	4,305	1,355
10	3,690	1,432
11	3,075	1,506
12	2,460	1,576
13	1,845	1,643
14	1,230	1,707
		$16,230

rate has the greatest effect on optimal replacement policy, (*b*) the tax rate causes only slight differences in optimal replacement policy, (*c*) the depreciation method used has little effect on replacement age, and (*d*) the optimal replacement age is longer than that normally observed to be followed by full-time, commercial farmers, particularly at the higher discount rates. These last two conclusions support Chisholm's results.

However, contrary to Chisholm's results, additional first-year depreciation and particularly investment credit did affect optimal replacement age. With these terms in the model, the optimal replacement age was from one to four years less than without them for the lower discount rates. There was no change for after-tax discount rates greater than 5% and, as would be expected, the differences tended to be larger the higher the tax rate. As can be seen in table 3, investment credit causes most of the change, while using additional first-year depreciation alone in the model tended to lengthen the optimal replacement age in the 50% tax bracket.

We were also unable to verify Chisholm's results as presented in his table 2 for the U.S. income tax situation at the 5% discount rate. A possible explanation for this is that in calculating the investment credit that can be taken on a tax-free exchange of an used asset for a new one, Chisholm may have made an error. It is commonly assumed that investment credit can be taken only on the cash difference or "boot" on such a trade. However, Treasury Regulation Section 1.46-3(c)(1) permits investment credit to be taken on the cash difference plus the adjusted tax basis on the used asset traded in (i.e., on the beginning tax basis of the new asset). Chisholm's results appear to be correct when investment credit is taken only on the cash difference on a trade-in. This same error may account for the different conclusions on the effects of investment credit on optimal replacement age.

A major factor in determining replacement age in the model is the pattern of repair costs. If the pattern of repair costs experienced by farmers is different than the one used here, it may explain some of the difference in the theoretical replacement age calculated here and the actual replacement policy followed by farmers. Annual repair costs calculated using Bowers's equation increase at a decreasing rate. To test the effect of another repair cost function, one was generated with annual repairs increasing at an increasing rate but with the total repair cost remaining at $16,230. This repair function caused as much as a five-year change in the optimal replacement policy with the largest changes occurring with discount rates of 4% to 6%. Optimal replacement age was seven or eight years for after-tax discount rates of 0 and 1% and increased with the discount rate to become twelve or fourteen years at a 15% discount rate. Again, these results were affected little by tax rate or depreciation method used.

One of the factors contributing to the long replacement interval is the rapid depreciation during the first year. The nearly 40% loss in market value the first year represents a major cost to be borne by an early replacement policy. Other factors that would be expected to lengthen the replacement age are the income tax regulations that require a useful life of six years or longer before additional first-year depreciation can be taken and seven years for the full 7% investment credit.

The differences in present value (cost) for different replacement ages were small in many instances. This indicates a small cost associated with a "too early" replacement policy. A factor that would help justify and explain a shorter replacement policy is reliability. Realistically, as a machine ages, there is an increasing probability of a

breakdown or a loss in reliability causing not only increasing repair costs but costs resulting from a loss of timeliness. The cost of a delay in planting or harvesting may be substantial and may have an impact on the replacement decision. If farmers view this loss of reliability as a cost, it would help explain a replacement policy more rapid than that calculated here.

We could find no data on breakdown probabilities as a function of age or a reliable measure of the resulting loss. To illustrate the possible effects of a loss in reliability, a hypothetical set of probabilities were developed that increased at an increasing rate with age. A constant nonrepair cost was assumed for each breakdown with the resulting "reliability loss function" going from $47 in year 1 to $2,345 in year 14. The results from including these costs in the model are shown in table 4. Reductions in the optimal replacement age were much greater, particularly at the higher discount rates, than for any other modification of the basic model that we tried. The dominant seven-year replacement age indicates that the investment credit eligibility rules may have had some influence in this case.

While the tax regulations that permit using double-declining balance depreciation and taking additional first-year depreciation and investment credit did not have as large an effect on optimal replacement age as might be expected, they did affect the present value (cost) of obtaining the constant annual stream of tractor services. The values for selected tax-rate–discount-rate combinations under various tax regulations are shown in table 3. The effect of these tax regulations is to lower the present value (cost) of any replacement policy. This result has probably, in part, encouraged the trend towards larger equipment and the substitution of machinery for labor. The net result is a larger overall investment in farm machinery than would have existed without these incentives.

To test the effect of lowering the useful life required by income tax regulations for assets to be eligible for additional first-year depreciation and investment credit, results were obtained for the case in which both deductions could be taken in full with a three-year useful life. There was no change in the optimal replacement age when compared to those calculated under the current eligibility rules. However, an increase in the investment credit rate does reduce the optimal replacement age. Using the 10% rate permitted in 1975 and 1976 caused a one- or two-year reduction in the replacement age for after-tax discount rates of 5% or less when using double-declining balance depreciation.[3]

[3] A change in the income tax regulations may also affect the

A U.S. tax policy that permits double-declining balance depreciation, an additional first-year depreciation, and investment credit for farm equipment has encouraged some changes in optimal replacement age with the amount of change depending on the tax bracket and after-tax discount rate. However, the optimal replacement ages from the model are longer than observed on many farms, indicating that there are factors not included in the model that affect farmers' replacement decisions. Some possible explanations are: (*a*) a repair cost pattern that is different than either considered in this study, (*b*) the loss in reliability as a machine ages, (*c*) the desire or need to replace earlier with a larger machine, and (*d*) a desire to replace earlier in order to utilize the improved technology incorporated in the replacement.

Technology has continued to improve the capacity, efficiency, convenience, and operator comfort incorporated in farm equipment. These continual technological improvements likely contribute also to a shorter replacement policy. When the authors showed the early results of this study to a farmer and then asked him why he traded tractors at a much earlier age, his immediate response was "because the new one is always better."

market values of used machinery. The net effect may be little or no change in the optimal replacement age.

Effects of Tax Depreciation Policy and Investment Incentives on Optimal Equipment Replacement Decisions: Reply

Anthony H. Chisholm

The central concern of my paper was to develop a replacement model that incorporated the effects of income tax policy and to apply the model to a case study of the effects of Australian income tax regulations on optimal tractor replacement ages. On the basis of a considerably more restricted application of my model, I concluded that U.S. income tax regulations would not appear to influence significantly the optimal timing of replacement.

In their comment, Kay and Rister seek to extend my work by undertaking a more extensive empirical analysis of the effects on replacement of the U.S. income tax regulations. Employing a present value model similar to relation (3) in my paper (p. 777) but using another set of data, Kay and Rister find that contrary to my results at lower discount rates (≤ 5%) the U.S. investment credit lowers the optimal replacement age. In addition, they were unable to verify my result in table 2 for the U.S. income tax situation at a 5% discount rate. The reason for being unable to verify this result is due to a small calculation error in my paper. The optimal replacement age at the 5% discount rate should be eight years (annuity cost $500) and not eleven years (annuity cost $502). I did not make the error suggested by Kay and Rister, namely, to assume that the investment credit can be taken only on the cash difference or "boot" on a trade in.

That the U.S. investment credit introduces a potential bias towards earlier replacement once an asset has been held for seven years is beyond dispute. The bias is attributable to the fact that the annuity value of the investment credit progressively decreases from the seventh year onwards, i.e., from the first year in which the full investment credit may be claimed. This is clearly illustrated in my table 3 in which annuity values for the U.S. investment credit and for various depreciation methods (relative to a neutral depreciation allowance) were presented.

My reason for concluding that the U.S. income tax regulations would not appear to influence significantly the optimal timing of replacement is that the bias introduced by the investment credit is very small both in absolute terms and as compared with the former Australian investment allowance. That is to say, for the U.S. investment credit, the absolute differences between annuity values for different replacement ages are comparatively small. The annuity values presented in table 1 illustrate this point. These annuity values, taken largely from table 3 in my original paper, were calculated using a 10% rate of discount. The figures clearly illustrate the relatively small replacement bias of the U.S. investment credit as compared with that of the former Australian investment allowance. For farmers in high tax brackets, the bias of the latter was of sufficient magnitude to make tractor replacement at age one year optimal, as against an eleven-year optimal replacement age for farmers in low tax brackets. The impact on replacement of the U.S. investment credit would be substantially increased if, like the former Australian investment allowance, it could be claimed in full regardless of the age at which an asset was replaced, as is shown by the annuity values in the right-hand side column of table 1. Unlike the investment allowance, however, the incentive towards early replacement provided by the investment credit is independent of a farmer's tax bracket providing, of course, that a farmer has positive tax payments from which to deduct the credit. It is especially important in these circumstances to keep in mind the partial equilibrium nature of the analysis. Initial substantial incentives towards early replacement would be at least partially countered by adjustments in the structure of secondhand tractor prices if current eligibility restrictions on the U.S. investment credit, relating to asset age at time of replacement, were to be completely removed.

To this point I have not discussed the effects of different methods of depreciation on the timing of optimal replacement because both my results and those of Kay and Rister indicate that these effects are fairly minimal. The results in table 1 show that, as compared with neutral depreciation, the former Australian accelerated depreciation allowance has a bias towards later replacement, but for my data the bias was too small to alter the optimal replacement age. Kay and Rister found that the U.S. additional first-year depreciation alone also induces a small bias toward later replacement and that for their data the optimal replacement age was in fact lengthened in the 50% tax bracket.

Finally, Kay and Rister state that the optimal

Anthony H. Chisholm is a senior lecturer in economics at the Australian National University.

replacement ages from their model are longer than those actually observed on many farms and give several possible explanations. They suggest that the desire to replace earlier in order to utilize the improved technology incorporated in the replacement may be the most important factor. Although I did not make any attempt to discuss these issues in my paper, there are some indications from farmer surveys that in Australia the risk of breakdown (loss in reliability as a machine ages) is a more important factor influencing earlier machine replacement than the technological improvements incorporated in new models.

Books Reviewed

Buse, Rueben C., and Daniel W. Bromley. ***Applied Economics, Resource Allocation in Rural America.*** **Ames: Iowa State University Press, 1975, x + 623 pp., price unknown.**

This book was designed as an introductory text in agricultural economics with special emphasis on the development of microtheory and its application to rural problems. It contains a descriptive or perspective section. The microtheory section includes production and cost principles, market price determination, comparative advantage, and market structure. The final section is a discussion of rural economic problem areas including low farm income, rural poverty, community development, the agribusiness sector, and natural resource economics. A considerable amount of descriptive material is included in the text, as well as a considerable amount of microtheory.

The text will be well received by students from the point of view of the clarity of presentation, the inclusion of easy-to-understand definitions, and the sizable amount of data included in the book. They may find some parts of the presentation a bit dry, as the authors attempt to obtain completeness of coverage by touching on more than just the central factors involved with the topics of the text.

The material included in the text seems wisely chosen. It has a wide relevance to students with a broad interest in agricultural economics, and important topics have received attention and analysis. At points some teachers will feel that the text has gone into more depth and detail than would normally be expected of students in a beginning course in rural microanalysis. This is not a serious matter, however, because a professor need not assign every page of the text.

Teachers will appreciate this text particularly because of the analytical approach taken to the several topics for consideration in depth. This is probably the greatest contribution of this text to the university student. However, an even greater focus on economic policy issues could have reinforced the learning of the economic principles and brought increased understanding to policy development.

The text is well written, easy to understand, and will fit the needs of a great many college classrooms. As is true with most textbooks in this area, the amount of material that professors will ask their students to read from it may nearly overwhelm them.

I would have liked to have seen an even greater integration of the development of economic principles with their application to real world problems. Even though there is a good deal of application of economic theory to solving important problems in the text, often this application and the development of the theory are many pages apart.

The timing of the printing of this textbook and a basic change in the market and income situation of American farmers is unfortunate. Even though this text is published in 1975, the farm-policy section and the farm-production data are all from a 1972 perspective, focusing on overproduction and low income. Today's students will find this section of the text quite dated. However, the challenge of the classroom teacher is to bring the material up to date, and with such a rapidly changing situation we cannot criticize the text too much for being born at the moment of a dramatic economic change.

The textbook has obviously been prepared with a great deal of care and thought. Particularly appreciated are the annotations in the reference section at the end of each chapter, giving a better idea of the nature of the potential contribution of this reference to the student's understanding.

As a complement to their text, Buse has prepared an accompanying "Study Guide for Applied Micro Economics." This study guide contains helpful introductory material in each of the areas covered and several questions to test comprehension. The answers to all questions are contained in the final pages of the guide. This study guide is particularly well done. It does not correspond in topic coverage directly with the text. The comparative advantage section is superb. The study guide is the best that I have seen, and if its emphasis is consistent with course objectives it would be a boon to understanding.

This text deserves serious consideration on the part of most teachers of introductory agricultural economics in the nation's universities and junior colleges.

Robert W. Taylor
Purdue University

Gulland, J. A. ***The Management of Marine Fisheries.*** **Seattle: University of Washington Press, 1974, vii + 198 pp., $18.50.**

With the third law of the Sea Conference methodically moving coastal fishery controls to 200 miles and with the World Food Conference concerned about food resources, this is a very timely book. Gulland is well respected in the fisheries management field, having written many articles, papers, and books in that area since 1956. He worked for a number of years at the Fisheries Laboratory in Lowestoft, England, where he specialized in population dynamics. He has been concerned with providing scientific advice to various international

commissions such as the Northeast Atlantic Fisheries Commission, the International Commission for the Northwest Atlantic Fisheries, and the International Whaling Commission. Since 1966 Gulland has been in the Fisheries Economics and Institutions Division, Department of Fisheries, Food and Agriculture Organization of the United Nations.

Gulland's experiences and interests are clearly reflected in this book. There is an excellent chapter on Antarctic whaling that runs for twenty-eight pages and another chapter on North Atlantic trawl fisheries that consists of thirty pages.

For the newcomer to fisheries, there is an excellent chapter on the biological basis of management that helps the reader to understand terminology that is traditionally used by marine biologists. Although Gulland's early training was in mathematics, this chapter is understandable to anyone with a knowledge of algebra. While several very complicated mathematical models have been developed to describe fishery population dynamics, Gulland does not use them because the quality of the data available is usually so poor that the models based on these data may only vaguely resemble reality.

One cannot directly determine inventories in fisheries as one can in forestry or farming, where one can see or count the size and number of trees, acres of land, or cattle of feed. The quantity of fish, or the "biomass," is estimated from the relation of total catch to total fishing effort—catch per unit effort. Gulland's discussion on the critical need in fisheries management for adequate data on fishing effort needs to be emphasized.

Historically, the objectives in fisheries management have been quite different from those in agriculture. In fisheries the most widely used objective is the goal of maximum sustainable yield, which Gulland defines as the greatest physical yield that the stock can produce year after year (p. 107). Gulland does recognize that maximum net economic yield or maximum rent are alternative fishery management objectives that have been proposed by Crutchfield and Zellner, Christy and Scott, and Crutchfield and Pontecorvo. While Gulland does mention optimum management strategy, nowhere does he mention "optimum yield" as an objective that is currently being discussed in the National Marine Fisheries Service and state fishery management agencies. To the reviewer, this chapter—the fifth—is by far the most interesting one in the book and should have been the second chapter because of the need to understand the objectives of fisheries management early in the book.

There is a good review of the techniques of fisheries management now in use. There was, however, no discussion of alternative methods such as pricing or landing fees and subsidies that are under consideration. With only a few exceptions, the present management techniques have not prevented the sequential overfishing of the most valuable fishery stocks.

Multispecies fisheries and separate fisheries on different stocks in the same area that interact are reality. Yet nearly all of this book is based on individual species models. Gulland recognizes this when he says "to an excessive degree the methods consider the individual species in isolation, without considering the entire eco-system in which they live" (p. 184).

Gulland is also concerned that international fisheries management will not advance rapidly until there are people "familiar with the biological complexities of the life of fish in the sea, and having the mathematical dexterity to carry out the necessary quantitative analyses" (p. 185). An understanding of microeconomics and industry economics needs to be added to these requirements.

The management of marine resources is a problem of allocation—the allocation of scarce valuable resources to people who are competing for them. Only once does Gulland recognize that these fishery resources are beginning to have value while they are still in the water (p. 189). Until management schemes are developed that deal with the value of these resources and do not treat them as "spoils," there shall be conflicts and problems in fisheries management.

For anyone working in international fisheries management, a review of chapter 7 is essential. In table 8 there is a listing of the international bodies concerned with fisheries management, with acronyms, 1972 membership, date established and auspices, headquarters, eligibility for membership, area of competence, resources covered, and functions. This would be useful as a ready reference.

This is a very readable book on a very interesting subject. Graduate students looking for some challenging and timely subjects would find this book and area worthwhile.

There are both an excellent list of references at the end of each chapter and author and subject indexes.

Fred L. Olson
National Marine Fisheries Service
U.S. Department of Commerce

Lele, Uma. *The Design of Rural Development: Lessons from Africa.* Baltimore: Johns Hopkins University Press, 1975, xiii + 246 pp., $12.00.

This study commissioned by the International Bank for Reconstruction and Development is designed to be a sequel to the earlier Bank-sponsored study by John C. de Wilde, *Experiences with Agricultural Development in Tropical Africa*, published by Johns Hopkins University Press in 1967 in two volumes. It differs from the earlier study in focus in that much more attention is given to equity questions and problems of increasing income of the lowest income groups.

The study is based on seventeen rural development projects located in seven tropical African

countries: Mali, Cameroon, and Nigeria in western Africa, and Ethiopia, Kenya, Malawi, and Tanzania in eastern and central Africa. These projects and agencies that come up in assessing their performance generate over seventy acronyms that make the text tedious. Fortunately, a glossary of acronyms is provided.

There are two chapters on the characteristics of small farmers in tropical Africa, a chapter on agricultural extension and mass participation, one each on agricultural credit, marketing, social services, and training programs, and two on rural development planning and administration.

The book's major weakness is that because of the author's relatively shallow experience in Africa she misses much of the relevant literature. Yet the book makes a contribution. Just the experience generated from the seventeen projects reviewed yields many conclusions that, while not new, can bear further emphasis. This reviewer can only applaud the conclusion that development programs in Africa are "often based on inadequate knowledge of technical possibilities and their suitability to small-farm conditions" (p. 176). Or that development projects in Africa suffer badly "from poor knowledge of the socio-cultural and institutional environment" (p. 176). There are several short segments of chapters that provide important new data. Here, three pages in an early chapter on labor bottlenecks are particularly noteworthy, as are a page and a half in the same chapter on the sex division of labor and the role of women and two pages farther on in the text on the neglect of women by agricultural extension services in Africa. There is also a good brief discussion of the contribution and problems of tractors and ox plows among small farmers in tropical Africa.

Marvin Miracle
University of Wisconsin

Maynes, E. Scott. *Decision-Making for Consumers, A Guide to Consumer Economics.* New York: Macmillian Publishing Co., forthcoming.

Maynes has set out to write an introductory text for undergraduate students that emphasizes principles. He has chosen to avoid presenting historical data or facts that will quickly date his writings. He indicates in his preface that illustrations and examples of situations will be used to help the reader retain and reinforce the principles discussed. His objective is to help the student understand relationships between the broad economic principles that affect individual purchase decisions and the performance of the economy. The majority of the book (about 340 pp.) is devoted to individual purchase decisions and how consumers can more effectively satisfy their needs. The final section is concerned with consumer sovereignty. It embraces an overview of the issues (chap. 9), views of economists (chap. 10), and a critique of consumerists (chap. 11).

This book should be given serious consideration as an introductory text. Its readability and examples are major strengths. The initial chapters are a refreshing approach to the benefits derived by individuals who carefully search for and use information to choose among alternatives. His documentation of the value of a dollar saved should generate enthusiasm for the subject matter.

Maynes's second chapter introduces the use of microeconomic concepts for consumer use. The discussion of mental capital (memories) along with subjective and objective costs of searching for information as they relate to consumer payoffs is well done. He then develops the concept of marginality as a practical guide to consumers. The discussion of reasons why consumers fail to use information is good. A brief explanation of retailer ignorance would increase the objectivity of this discussion. My only concern is with his comment that economic theory must be modified to be more realistic and understandable to consumers. In fact, the theory is not "modified." The explanation and application to individuals versus firms or industries may be a modification of traditional presentations, but the principles endure. In fact, Maynes projects a cynical posture towards economics, economists, and business that pervades each chapter. Perhaps it is ego defense, but this seems unnecessary and even counterproductive.

Chapter 4, on acquisition and evaluation of consumer information, would benefit from the recognition of imperfect knowledge of individuals in various levels of the market channel. He implies sellers have complete knowledge and consumers are helpless to defend themselves. Many sellers are at least as ignorant about products and competitors as consumers. This chapter contains a section written by David Gardner concerning deception in advertising, which is very provocative. Unfortunately, it may be too advanced for the beginning student.

Maynes probably views chapter 3, "Product Quality: Meaning, Measurement, and Implications," as his major contribution. His discussion of critical scores and weights as a measure of quality is good. The section concerned with prices and quality is effective. He concludes that his example of a perfect information frontier (lowest price for a given quality level) also illustrates the effect of number of competitors on price. Although one would logically agree with the generalization that intensive retailer competition should be expected to result in the lowest prices possible, his empirical illustration contains evidence of one and two sellers on the perfect information frontier.

"Product Testing and Consumers Union," chapter 5, makes a clear plea for the use of their services. One expects to find an application blank at the end of the chapter. Maynes's long affiliation with Consumers Union is clearly stated, so this chapter is not only appropriate but expected.

Chapters 6 and 7 provide many helpful ideas to improve one's art of negotiating and use of decision

rules. The cases illustrate problems as well as success and should prove practical to nearly anyone. "Individual Redress: The Righting of Consumer Grievances," chapter 8, emphasizes what individuals can do to prevent grievances. In addition, practical guides for redress and appropriate cautions are presented. He illustrates that one should not expect to be successful with all attempts even if his position is correct.

The final section dealing with consumer sovereignty is an objective treatment of issues and alternative views of economists. The book was reviewed in draft form, and the final chapter was not available. Presumably, it will add to the cohesiveness of the first two chapters of this section and lead the reader to a set of conclusions. In fact, one acquires the feeling that he is being prepared for such a climax.

In summary, it is an interesting book for consumers to use to help them better their position in the market place. An intensive knowledge of economic principles is not required. It is not intended as an economics of consumption text. Maynes focuses on his objectives and provides the reader with the guide he promised. An experienced teacher with a sound economics background could use the text effectively. If the instructor lacked a sound economics background, students may develop an unfairly critical view of economics.

William J. Vastine
Texas A&M University

Montgomery, John D. *Technology and Civic Life: Making and Implementing Development Decisions.* Cambridge, Massachusetts, and London: The MIT Press, 1974, 239 pp., $12.50.

It is difficult to argue with Montgomery's central point that policies set by the governments in most less developed countries must "devolve" so that most development programs are administered nearer the local scene to a greater degree than is presently the case. As a corollary, local participation must figure crucially in the decisionmaking process. Community support, we have long known, is more easily won in that manner, and it makes easier the acceptance of useful new ideas and practices. Also, even centrally stationed functionaries then become aware of local problems and needs. Nothing is more discouraging to see than the waste and human suffering involved in a large, centrally organized country with a primary capital city (or even large state capitals) where vaccines arrive after the epidemic, fertilizer after planting when side-dressing will not do, food after the plague, and bales of hay after cattle have already died from lack of feed. Equally disconcerting is the developer (be he a national or a foreigner) who arrives with a perfectly acceptable "cure" that might well work because it fits in with the local mores, but he is ignorant of them and fails to use them. (Some of these practices and beliefs are inadequate to the task, of course.) All of us involved in development work have our shocking stories of development failure, and one only hopes (probably in vain) that there are not too many.

Montgomery sets forth an admirable goal for development administrators when he says that "*modernizing the behavior of citizens* [is] . . . *a primary task of development administration*" (his emphasis, p. 82). The major contribution Montgomery would like to make in this monograph is expressed in this sentence: "Operations designed to change mass public behavior . . . are likely to be better performed, better understood, and more clearly integrated to local needs if the function is delegated to the lowest levels at which they can be conducted and personnel are drawn from a local base whenever possible" (pp. 77–78). He mentions the panchayat as an example. But Montgomery is realistic in saying that third world villages, as many third world countries, are not necessarily democratic (p. 95). (He knows the "local participation" in his scheme is not foolproof!)

Early in the book he takes us first on what seems to me an unnecessarily long and detailed discussion of Western development. Again, I find myself in agreement with Montgomery's central point, but I wish he had stated it more succinctly. What I hear him saying in this section of the book is simply that the "process competition" that characterized development in the west will repeat itself in the third world only at great peril, human suffering, and social unrest. "The means for protecting citizens against these traditional forms of exploitation constitute one of the principal concerns of democratic theory" (p. 93).

The readers of this journal particularly will appreciate this quote referring to U.S. and western technology in LDC's:

> New industrial processes close old factories, or at least displace elements of the work force unable to master them. In agriculture as well as industry, new processes often require investment that is out of the reach of smaller or less prosperous competitors, and the consequences of technological advance may therefore be farm foreclosures, retreat to the crowded cities, and corporate farming (p. 89).

To Montgomery, the results of incidents like this are clearly "widespread social losses, to say nothing of strikes and lockouts, sabotage, and various forms of terrorism" (p. 91). He argues that society may well have to use violence to minimize the public cost of such conflict, but he suggests "not so much responsive violence [Is this a euphemism for "repression"?], which only enhances the social loss, as better intelligence, more adequate forms of negotiation, and more sensitive political processes" (p. 91). I hope this latter optimism is in the realm of the art of the possible, but I wish I could

write as sanguine a prognostication, however tentative.

I would recommend that the reader first work through chapter 6 to see where Montgomery's arguments are leading. He believes in development progress (peasant participation) as a "first-order decision"; this will work with relative smoothness only if there is a technological "fit." The literature is quite complete, if not redundant, on "choice of technology," and we need not belabor it. But it is interesting to hear a distinguished political scientist phrase it in this manner, "technologies can be said to possess their maximum developmental potential when they are designed to offer to large and identifiable citizen groups new standards, new opportunities for investment, and new means of integrating competitive private interests with public interests" (p. 192).

The "second-order decision" (p. 203) is unrealistic to me: "choice of implementing agency." Here, I think Montgomery is in more intellectual and practical trouble. I know that political structures in many LDC's to which he refers are not committed to the kind of participatory change Montgomery advocates; ruling elites—except in very unusual circumstances—are not committed to strengthening the group that threatens their supremacy. Montgomery runs down a list of possibilities, obviously to convince us that this problem can be circumvented. Maybe lower echelon administrators with more contact with those who desire change can do the job? Perhaps public industrial enterprises with less government connection can promote more participation? Could the civil service (presumably lower level), cooperatives organized by the agricultural ministries, or voluntary organizations do the task? And there are more examples. He claims "reliance on traditional government agencies for development purposes seems to be going out of style" (p. 207). I do not happen to think he is correct. In fact, I think he is dead wrong. Planning bureaucracies, Ministries of Agriculture, Departments of Exchequer, etc., are very much under the thumb of the central government; by definition, they are its administrative organs and do its bidding. The public official, however low level, who steps out of line to promote something the government does not want—such as a complete change of social structure—will be affected by raises and promotions and hiring-and-firing decisions emanating from the center of the agency, not from the peasant or peasant groups. True, there are mavericks in any agency. But their influence is marginal at best. Charismatic leaders from this group who promote radical change are probably even more rare.

His "third-order decision" is that of providing incentives, something with which few of us would quibble and with which I will spend no more time.

I cannot leave this generally favorable review without severely criticizing Montgomery's analysis of land reform on pages 72–73: "A study of 25 major land reform efforts that took place in the twentieth century showed that in 16 cases the governments succeeded in improving the security of the peasants' tenure, but only 11 increased their income, and only 9 enhanced their political power" (p. 72). How can we compare Japan's and Taiwan's long-standing reforms that had all of their countries' infrastructure in place at the time of reform with Bolivia's comparatively new reform (1953), Bolivia being an exceedingly poor enclave country that had practically no overhead capital at the time of reform and still has little (although living standards have gone up somewhat)? What about Mexico, a country that created a land reform and proceeded to pour most of its public (and private) funds into the nonreform sector? And to say that Indonesia, Colombia, Brazil, West Pakistan, Ecuador, and Guatemala have had a reform is folly indeed.

I agree that decentralization must be a precondition of any agrarian reform. Certainly, it is the one way to have any hope of the reform being successful. But let us not give credit where it is not due.

This book is well worth having in your library.

Announcements

Annual Meeting, 1976

The annual meeting of the American Agricultural Economics Association will be held 15–18 August at Pennsylvania State University in University Park, Pennsylvania. Professor James Holt is chairman of the local arrangements committee. The Northeastern Agricultural Economics Council will be meeting jointly with the AAEA.

1976 Meeting Allied Social Sciences Association

The American Agricultural Economics Association will meet jointly with the Allied Social Sciences Association in Atlantic City, New Jersey, 16–18 September 1976. Tentatively, sessions are being scheduled as follows: (*a*) contemporary economic issues (round table discussion), (*b*) financing local government services, (*c*) fiscal policy issues, and (*d*) economics of the household. Program details are available from Kenneth R. Farrell, President-Elect, AAEA, Economic Research Service, U.S. Department of Agriculture, Washington, D.C. 20250.

Change in Farm Foundation Program

Effective 1 May 1976, the Farm Foundation will provide financial and staff support for research activities on an ad hoc basis, rather than through ongoing regional research committees. This change applies only to research, not extension. The purpose of the program change is to strengthen the catalytic role of the Farm Foundation in social science research. No change is proposed in the Foundation's policy of working with the land grant colleges, the U.S. Department of Agriculture, and related organizations. The new program is not a grants program. The Foundation staff will continue to help develop and participate in the activities it supports. As in the past, researchers and other individuals will be brought together to specify research problems and needs, to develop research strategies, or to seek improvements in data and research methodology.

Activities may be instigated by the Foundation staff or by requesting organizations and individuals. Requests for support may come from any of the following: researchers, experiment station directors and deans, department heads, research groups or planning committees in the land grant-U.S. Department of Agriculture system, government agencies, extension personnel, and other users of research.

The Foundation intends to maintain its informal style. Rather than require overly formal proposals, the request should state the purpose, the procedure, intended results, duration, and the nature of support desired. As in the past, expenses of the activities supported will be paid directly by the Farm Foundation. Requests may be made for support of a single activity, such as one meeting, or for a "package" (sequence of activities), with a maximum of two years' support. The activity may be multistate, regional, or national. It may focus on a commodity issue, a research methods issue, or a policy issue.

Three main criteria will be used: the importance of the problem, professional and institutional improvement, and the likely payoff. Highest priority will be given to activities concerned with agricultural and rural problems that the Foundation views as significant to the future well-being of rural people. Applied research, the development of more basic knowledge, new theoretical approaches, and methodological or data improvements will be given equal attention. Activities to strengthen the capability of professionals and their institutions to produce useful research knowledge will be supported, provided that they are treated as "means" rather than as "ends." Activities involving researchers from smaller land grant colleges will be considered carefully in this context. Included in the payoff criterion are questions such as the following. Is the activity likely to produce significant results in the near future? Is the "spin off" potential high? Does the activity reflect new thinking? Use of these criteria will depend largely on the judgment of the Foundation staff, not on formal grading or weighting techniques. Further guidelines may be forthcoming as program experience is gained.

The initiators of each activity will be expected to provide a short report on the activity written in such a way that it will indicate to other researchers and administrators, as well as certain users of research, new insights emerging from the activity. The Foundation will not automatically support the publication of proceedings of activities such as conferences and seminars. Separate requests for such support will be required.

Requests for support should be made to R. J. Hildreth, Managing Director, or W. Neill Schaller, Associate Managing Director, at the following (new) address: Farm Foundation, 1211 West 22nd Street, Oak Brook, Illinois 60521.

AAEA Committee Structure, 1975–76

AAEA Representative to the Agricultural Development Council Research and Training Network Program

C. Peter Timmer, Cornell University

AAEA Representative to the Bureau of Census Advisory Committee on Agricultural Statistics

M. L. Upchurch, University of Florida

AAEA Representative to Federal Statistics Users Conference

Norman M. Coats, Ralston Purina Co.

AAEA Representative to the National Bureau of Economic Research

Harold G. Halcrow, University of Illinois

AAEA Representative to the National Research Council

John C. Redman, University of Kentucky

Alternative Publications

Verner G. Hurt, Chairman, Mississippi State University, 1975
Harold F. Breimyer, University of Missouri, 1975
Ben C. French, University of California, Davis, 1975
Glenn E. Heitz, Federal Land Bank of St. Louis, 1975
Paul E. Nelson, Economic Research Service, USDA, 1975
Stephen C. Smith, University of Wisconsin, 1975
Glen V. Vollmar, University of Nebraska, 1975

American Statistical Association, AAEA Joint Advisory Committee on Agricultural Statistics

R. James Hildreth, Chairman, Farm Foundation
Dean E. McKee, John Deere and Co.
Luther G. Tweeten, Oklahoma State University

Audit

James E. Criswell, Chairman, University of Kentucky, 1970
Larry D. Jones, University of Kentucky, 1974

Awards

Paul L. Kelley, General Chairman, Kansas State University, 1974

Distinguished Extension Programs

Everett Peterson, Chairman, University of Nebraska, 1974

Personnel

Agricultural Development Council

Appointments: William L. Collier, former council associate at Bogor, Indonesia, is in the Department of Agricultural and Resource Economics, University of Hawaii, Honolulu, for one year; **Max R. Langham,** formerly at University of Florida, is a research officer for the Regional Research and Training Program, Singapore.

University of Arizona

Appointments: John L. Fischer, professor of agricultural economics, is the coordinator, Africa Programs, Consortium for International Development; **James C. Wade,** formerly at Iowa State University, is an assistant professor of agricultural economics and assistant agricultural economist.
Return: William E. Martin, professor of agricultural economics, is back from a sabbatical spent at the Food Institute, East-West Center, Honolulu, Hawaii.

University of California, Berkeley

Appointment: Sidney Hoos, former university dean of academic personnel in the University of California System (statewide), is a professor of agricultural and resource economics, economics, and business administration.
Honor: Sidney Hoos has been elected a member of the Canners League of California Hall of Fame.

University of California, Davis

Appointments: Ben C. French, professor, is the chairperson of the Department of Agricultural Economics, effective July 1976.
Leave: Warren E. Johnston, professor, is spending his sabbatical in the Department of Farm Management, Lincoln College, Christchurch, New Zealand, July 1976–June 1977.

Cornell University

Appointments: Olan D. Forker, professor of marketing, is the chairman of the Department of Agricultural Economics, effective April 1976; **Wayne Knoblauch,** Ph. D. Michigan State University, is an assistant professor of farm management and production economics, effective May 1976.
Leaves: John W. Mellor, professor of agricultural economics, is the chief economist for the Agency for International Development, Washington, 1976–77; **Bernard F. Stanton** is a visiting fellow in the Development Studies Center, Australian National University, Canberra, May–August.
Retirement: Edward A. Lutz, professor of public administration, effective June 1976.

University of Florida

Appointments: Peter Jon Van Blokland, formerly at the University of Illinois, and **Robert L. Degner,** formerly at Texas A&M University, are assistant professors; **W. Gordon Kearl,** on leave from the University of Wyoming, is a visiting professor, January–July; **Karl Kepner,** formerly at Purdue University, and **J. Robert Strain,** formerly at Iowa State University, are professors; **Burl F. Long,** on leave from the Virginia Polytechnic Institute and State University, is a visiting professor, March–September; **Reza Soltani,** on leave from Pahlavi University, Shirza Iran, is a U.S. Agency for International Development postdoctoral trainee, 1976; **Ronald Ward,** formerly in the Florida Department of Citrus, is an associate professor.
Reassignments: Bernard W. Lester is a deputy director, Department of Citrus, Lakeland; **Daniel S. Tilley** is an assistant professor in the Florida Department of Citrus.
Retirement: G. Norman Rose has left after 32 years of service.

University of Georgia

Appointment: William Anderson Thomas, Ph. D. Clemson University, is an extension marketing economist.

University of Guelph

Appointments: Fred Buzzelli, chartered accountant, is a lecturer in agricultural business; **Janos Hrabovsky,** on leave from the Food and Agriculture Organization, is a visiting professor in economic development, April–August; **Steve Thompson,** M.B.A. University of Western Ontario, has been appointed lecturer in farm and financial management.

Iowa State University

Appointments: James D. Libbin is a research associate; **James M. McGrann,** former assistant pro-

ASCS: Agricultural Stabilization and Conservation Service; CED: Commodity Economics Division; EDD: Economic Development Division: FDD: Foreign Development Division of ERS; NEAD: National Economic Analysis Division of ERS; NRED: National Resource Economics Division of ERS; SCS: Soil Conservation Service.

fessor at Texas A&M University, is an assistant professor.
Resignation: John A. Otte, former research associate.

University of Kentucky

Appointment: David Heisterberg, M.S. University of Missouri, is a farm management specialist, Extension Division.

University of Maryland

Appointment: Billy V. Lessley is acting chairman of the Department of Agricultural and Resource Economics.

University of Minnesota

Appointments: Wallace C. Hardie, M.S. North Dakota State University, is a research specialist in dairy economics; **Ian C. Wills,** Ph.D. University of Illinois and a member of the Faculty of Economics and Politics at Monash University, Clayton, Victoria, Australia, is a visiting associate professor, January–June.
Leave: James P. Houck, professor, is at North Carolina State Agricultural and Technical State University, winter 1976.

University of Missouri

Appointment: Loyd K. Fischer, on leave from the University of Nebraska, is a visiting professor of natural resource economics.
Honors: Thomas G. Brown received a National Council Certificate of Recognition from Epsilon Sigma Phi; **Carl Utterstrom,** M.S. University of Missouri, received first place in the American Institute of Cooperation's M.S. thesis competition.

University of Nebraska

Appointment: J. David Aiken, J. D. George Washington University, formerly with NRED ERS, is a water specialist in the Department of Agricultural Economics.

University of Nevada

Appointments: Edmund R. Barmettler, professor, is an assistant to the dean of the College of Agriculture; **Chauncey T. K. Ching,** associate professor, is the chairman of the Division of Agricultural and Resource Economics; **Ronald Shane,** Ph.D. North Carolina State University, is an assistant professor of agricultural and resource economics.

New Mexico State University

Appointment: Michael Cook, Ph.D. University of Wisconsin, is working in the area of agricultural marketing.

Oklahoma State University

Appointments: James E. Casey, Jr., formerly at Texas A&M University, **Loren L. Parks,** formerly at the University of California, Davis, and **Joseph E. Williams,** formerly at Iowa State University, are assistant professors in production economics.

Oregon State University

Appointment: Roger G. Kraynick, Ph.D. University of Colorado, is a research associate.
Honor: Frank S. Conklin, associate professor, received the R. M. Wade Award for Outstanding Teacher in the School of Agriculture for 1975.

Pennsylvania State University

Appointment: C. Edwin Young, Ph.D. North Carolina State University, is an adjunct assistant professor of resource economics.
Retirement: C. William Pierce is a professor emeritus of agricultural economics after 29 years of service.
Honor: Clare A. Becker, professor of agricultural economics, received the Distinguished Service Award from the Pennsylvania Association of Farmer Cooperatives.

Purdue University

Appointments: Oscar Goldman is a temporary assistant professor of agricultural economics and an investigator on a National Science Foundation project entitled "Evaluating Milk Order Alternatives"; **Donald A. Hilger** is a grain market analyst; **William H. King** is a community development analyst; **Patrick D. O'Rourke** is a program development coordinator; **Gary Van Hoozer** is a temporary instructor and a grain market analyst; **James K. Whittaker** is an assistant professor of agricultural economics and is researching and teaching in production economics and farm management.

Rutgers University

Retirement: George W. Luke, professor of agricultural economics and marketing, department chair-

man (1957–70), and member of the Governor's Farmland Assessment Committee.

South Dakota State University

Appointments: Ardelle Lundeen, Ph.D. Iowa State University, and **Patrick A. Lyons** are assistant professors.
Leave: John E. Thompson, head of the Economics Department, is spending his six-month sabbatical in Washington, England, and Scandinavian countries.

Texas A&M University

Appointments: Gary D. Condra, former research associate at the Water Resources Institute, is an area extension economist-management at Ft. Stockton; **Milten E. Rister,** former research assistant, is an instructor in farm management; **Charles R. Taylor,** former assistant professor of agricultural economics and agricultural entomology at the University of Illinois, is an assistant professor; **Richard Trimble,** former assistant professor of agriculture and extension economics at the University of Guelph, Canada, is an extension specialist-management.

U.S. Department of Agriculture

Appointments: Robert Pfeiffer, Ph.D. University of Missouri, is a research economist with ERS at Little Rock, Arkansas; **John T. Steele,** former associate professor at Texas A&M University, is with the International Training Division.
Appointments in NEAD: Marilyn Altobello, Ph.D. University of Massachusetts, and **Timothy Baker,** formerly at Michigan State University, are with the Inputs and Finance Program Area; **Gene K. Lee,** formerly at Washington State University, and **Joseph Roop,** formerly with the Office of the Director at Large, Western Association of Agricultural Experiment Station Directors at Berkeley, California, are with the Aggregate Outlook Program Area; **Robert R. Miller,** formerly with CED's Dairy Group, is the economics editor of the ERS monthly *Agricultural Outlook*; **Thomas Stafford,** formerly with the United Dairy Industry Association at Rosemont, Illinois, is with the Distribution Analysis Research Program Area.
Appointments in NRED: Larry Boone, formerly at Lincoln, Nebraska, is on a two-year assignment with the Agency for International Development in Costa Rica; **Norman D. Kimball,** formerly at Berkeley, California, is on a one-year assignment with the Food and Agriculture Organization, Tanzania; **Reuben N. Weisz,** former assistant professor at the University of Arizona.
Reassignments: Walter J. Armbruster, formerly with NEAD ERS, is a staff economist with the Agricultural Marketing Service; **John L. Okay,** formerly with SCS, is a program analyst with the Cooperative State Research Service; **Charles Palmer,** formerly with the Southwest Resource Program Group at Denver, is with the U.S. Forest Service at Denver; **W. Fred Woods,** formerly with NEAD ERS, is a public policy specialist with the Extension Service.
Reassignments in CED: Luigi Angelo and Ludwin Speir, formerly with ASCS, are with the Fruits, Vegetable, Sweetener, and Tobacco Program Area; **Robert W. Bohall,** formerly with the Fruits, Vegetable, Sweetener, and Tobacco Program Area, is the acting deputy director; **Edward V. Jesse,** formerly at Davis, California, is the temporary program leader of the Fruits, Vegetable, Sweetener, and Tobacco Program Area.
Reassignments in EDD: Tom Carlin, formerly with NEAD, is the leader of the Income Studies Program; **Robert Coltrane** is the leader and **Conrad Fritsch** is the project leader of the Manpower Studies Program Area.
Reassignments in NRED: Joseph R. Barse, formerly with FDCD, is working on a special project related to environmental studies; **Daniel J. Dudek** is with the Southwest Resource Program Group at Davis, California; **Paul Dyke,** formerly at Corvallis, Oregon, is with the Resource Projections and Analytical Systems Group; **Joe Green,** formerly at Upper Darby, Pennsylvania, is studying the economic impacts of coal and shale oil development at Fort Collins, Colorado; **Roger W. Hexem,** formerly in Washington, is with the Northeast Resource Program Group at Cornell University; **Robert McKusick,** formerly at Davis, California, is the leader of the Small Watershed and Resource Conservation and Development Program Area; **Arnold Miller,** formerly at East Lansing, Michigan, is with the Office of Management and Finance.
Resignations in CED: Hilarius W. Fuchs is with Continental Grain, New York State; **Wyatte L. Harman** is with Con-Agra, Nebraska.
Honor in CED: Preston E. LaFerney was accepted for fellowships in Congressional Operations through August 1976.

Washington State University

Appointment: Jagjit Brar, former assistant professor at Southeastern Louisiana State University, is an assistant professor.

University of Wisconsin

Appointment: Richard Schoney, Ph.D. Purdue University, is working in farm management extension.
Leave: Truman F. Graf is on leave to work in

Bucharest on agricultural marketing in Romania, March–June.

Return: Duncan A. Harkin is back after a two-year stay in the Philippines working on a cooperative project with the Agrarian Reform Institute, the University of the Philippines-Los Banos and the Land Tenure Center, University of Wisconsin.

Other Appointments

Robert A. Bain, Ph.D. Cornell University, is the officer in charge of the Livestock Commodities Section, Bureau of Agricultural Economics, Canberra, Australia.

Juan A. B. Belt, former research associate at Cornell University, is a staff economist at the Instituto Centro-Americano de Administracion de Empresas, Managua, Nicaragua.

John Bobbe, M.S. University of Missouri, is the director of marketing division of the National Farmers Organization, Corning, Iowa.

Peter H. Calkins, former research assistant at Cornell University, is head of the Department of Agricultural Economics, International Vegetable Research and Development Center, Taiwan.

William Lee Davis, M.S. University of Missouri, is an economist with the CIA.

Lloyd Allen Dever, Jr., M.S. University of Missouri, is a commodity analyst at Doane Agriculture, St. Louis.

James C. Fink, Jr., is with Chilton Research Services, Radnor, Pennsylvania.

Robert F. Glenn, Ph.D. University of Missouri, is an assistant professor at Southwest Missouri State University.

Albert N. Halter, former professor at Oregon State University, is at the Electric Power Research Institute, Palo Alto, California.

Van Harrold, M.S. University of Missouri, is a fieldman with Saganon Valley Farm Management Association, Lincoln, Illinois.

John Helmuth, formerly with the NEAD ERS, is a staff economist with the Commodity Futures Trading Commission.

James Hendren, M.S. University of Missouri, is with the Federal Land Bank, St. Louis.

James Lewellen, M.S. University of Missouri, is a trainee with the Federal Intermediate Credit Bank, St. Louis.

Russell F. McDonald, former state extension economist-marketing at Texas A&M University, is with the Commodity Futures Trading Commission, Washington.

James Stricker, M.S. University of Missouri, is the superintendent of the University of Missouri Forage Systems Research Center, Linneus.

Mohamad Yusoff Yahaya, M.S. University of Missouri, is a marketing economist with the Farmers Organization Authority, Kuala Lumpur, Malaysia.

Ph.D. Recipients by Subject

Agricultural Finance, Capital, Credit

Leslie Gene Carlow, B.S. University of Nebraska, 1968; M.S. University of Nebraska, 1972; Ph.D. University of Nebraska, "Capital in Nebraska Agriculture: Its Formation, Distribution, and Financing."

Richard J. Edwards, B.S. Cornell University, 1961; M.S. Purdue University, 1966; Ph.D. Purdue University, 1974, "The Cost of Assessing Property in Indiana, Iowa and Wisconsin: 1963."

Alan Kent Reichert, B.S. Miami University, 1968; M.S. Ohio State University, 1973; Ph.D. The Ohio State University, "The Effect of Bank Holding Company Growth in Ohio's Rural Capital Markets."

Agricultural Labor; Rural Manpower

Evonir Batista de Oliveira, B.S. Faculdade de Econ e Financa, 1962; M.S. Univ. Rural Minas Gerais, 1966; Ph.D. Purdue University, 1974, "Agricultural Employment and Land Reform in Brazil."

Sue Eileen Hayes, B.A. Stanford University, 1965; M.S. University of California, Berkeley, 1973; Ph.D. University of California, Berkeley, "Seasonal Workers in Extended Employment: Implications for Agricultural Labor Policy."

Roger Neil Sexton, B.Ec. Flinders University of South Australia, 1971; M.E. North Carolina State University, 1974; Ph.D. North Carolina State University, "Determinants of Multiple Job-Holding by Farm Operators."

Neil John Steeper, B.Ag.Ec. University of New England—Australia, 1964; M.Ag.Ec. University of New England—Australia, 1974; Ph.D. North Carolina State University. "A Portfolio Approach to Occupational Adjustment Applied to U.S. Farmers' Families, 1945 to 1970."

Agricultural Products: Demand, Supply, Prices

William T. Boehm, B.S. Wisconsin State University, 1970; M.S. Purdue University, 1972; Ph.D. Purdue University, 1974. "An Econometric Analysis of the Household Demand for Major Dairy Products."

Roe Everett Borsdorf, B.S. Kansas State University, 1957; M.S. Kansas State University, 1971; Ph.D. Kansas State University, "An Investigation into Forecasting Planted Crop Acreages in the Short Run as a Quantitative Measurement Tool for Agribusiness Management."

Wen Shyong Chern, B.S. Provincial Chung-Hsing University, 1964; M.S. University of Florida, 1969; M.S. University of California, Berkeley, 1971; Ph.D. University of California, Berkeley, "Supply Response and Price-Demand Relationships for California Processing Tomatoes."

Oscar Goldman, M.S. National University of Rosario, 1972; Ph.D. The Pennsylvania State University, "A Quarterly Econometric Model of the U.S. Dairy Subsector—1955–72."

Ralph G. Lattimore, B.S. Lincoln College, 1968; M.S. Massey University, 1971; Ph.D. Purdue University, 1974, "An Econometric Study of the Brazilian Beef Sector."

Chun-Lan Lee Liu, B.S. National Taiwan University, 1965; M.S. Southern Illinois University, 1970; Ph.D. University of Illinois, "Optimal, Temporal, and Spatial Pricing and Allocation of Wheat in the International Market."

Adolfo Martinez, B.S. Universidad Nacional de Colombia, Facultad de Agronomia, Palmira, 1970; M.S. Louisiana State University, 1973; Ph.D. Louisiana State University, "An Economic Analysis of Effects of Selected Quality and Non-Quality Factors on Prices of Medium and Long Grain Rough Rice in Louisiana."

Robert Alexander Milligan, B.S. Michigan State University, 1969; M.S. Michigan State University, 1971; Ph.D. University of California, Davis, "An Econometric Model of the California Dairy Industry."

Stanley Robert Thompson, B.S. California State Polytechnic University, 1968; M.S. Oregon State University, 1970; Ph.D. Cornell University, "An Econometric Analysis of Sales Response to Generic Fluid Milk Advertising in New York State."

Trevor Young, B.A. University of Nottingham, 1970; M.S. Victoria University of Manchester, 1972; Ph.D. University of California, Berkeley, "Grouping of Commodities in Demand Analysis."

Cooperatives and Cooperation

Wilmer A. Dahl, B.S. University of Wisconsin-Whitewater; M.S. University of Wisconsin-Madison; Ph. D. University of Wisconsin-Madison, "Alternative Financial Management Strategies for Local Farm Supply Cooperatives in Wisconsin."

Donald R. Schwartz, B.A. South Dakota State University, 1969; M.S. South Dakota State University, 1971; Ph.D. Purdue University, 1974, "Vertical Coordination in Cooperative Grain Marketing Systems."

The names of Ph.D. recipients are provided by departments of agricultural economics and by departments of economics with majors in agricultural economics. The list is for degrees granted in the calendar year 1975, unless otherwise noted.

Economic Development, Growth, and Planning

Suleiman Mufleh Arabiyat, B.S. Damascus University, 1965; M.S. University of Arizona, 1969; Ph.D. Mississippi State University, "Interindustry Analysis as an Aid in Planning for Economic Development in Underdeveloped Areas: Application to the Jordanian Economy."

Amir Baharuddin, B.S. Louisiana State University, 1970; M.S. Louisiana State University, 1971; Ph.D. University of Missouri, "An Economic Analysis of the Agricultural Development Potential for Southern Honduras."

Khairulah Dawalty, B.S. Kabul University, 1962; M.S. University of Wyoming, 1965; Ph.D. University of Tennessee, "A Two-Stage Estimate of Underemployment of the Male and Female Labor Force, by County, Tennessee, 1960 and 1970."

Bhupendra Maganlal Desai, B.A. University of Bombay, 1961; M.A. Sardar Patel University, India, 1963; Ph.D. Cornell University, "Relationship of Consumption and Production in Changing Agriculture: A Study in Surat District, India."

Arthur Lee Roy Ekholm, Jr., B.A. University of Texas, 1962; M.A. Texas Christian University, 1968; Ph.D. Oklahoma State University, "Regional Economic Adjustment to the Depletion of Groundwater and Petroleum: High Plains of Oklahoma and Texas."

Mohamed H. El-Hurani, B.S. Cairo University, 1969; M.S. Portland State University, 1972; Ph.D. Iowa State University, "Economic Analysis of the Variation and Development of the Wheat Subsector of Jordan."

Gafsi Salem, M.S. University of Tennessee, 1970; Ph.D. University of Minnesota, "Green Revolution: The Tunisian Experience."

Farrokh Ghobadi, B.A. Sacramento State College, 1969; M.S. Iowa State University, 1973; Ph.D. Iowa State University, "Estimated Impacts of Variation in Wheat Price Policy in Northern Iran.

Dennis Wayne Goins, B.A. Wake Forest University, 1970; M.E. North Carolina State University, 1972; Ph.D. North Carolina State University, "The Demand for Housing in Rural North Carolina."

Leonel Guillermo Gonzalez, B.S. University Rafael Landivar; M.S. University Rafael Landivar; Ph.D. University of Wisconsin-Madison, "Economic Development Potentials in the Production of Vegetables in Guatemala."

Robert A. Gray, B.S. Texas Technological College, 1951; M.Ed. Texas Technological College, 1956; Ph.D. Michigan State University, "Agricultural Export Potentials and Balance of Payments Aspects of the Nigerian Economy."

Kuo-Shiung Huang, B.S. National Taiwan University, 1962; M.S. National Taiwan University, 1965; Ph.D. University of California, Berkeley, "An Econometric Analysis of the Taiwan Economy, 1952–1969."

Morris T. Jones, A.B. Union University, 1966; M.S. University of Tennessee, 1968; Ph.D. University of Tennessee, "Fire Protection Services for Rural Tennessee Communities: A Benefit-Cost Analysis."

Jeung H. Lee, B.S. Seoul National University, 1957; M.S. Seoul National University, 1962; M.S. Iowa State University, 1969; Ph.D. Michigan State University, "Projections of Product Supply and Factor Demand under Structural Change for Korean Agriculture: A Systems Simulation Approach."

Thomas Harold Loftin, B.S. Mississippi State University, 1953; M.S. Mississippi State University, 1966; Ph.D. Mississippi State University, "An Economic Analysis of Rural Water Associations in Mississippi with an Estimated Costs per Customer by System Size."

Diego R. Londono, B.S. Universidad de Caldas, 1962; M.S. Oklahoma State University, 1970; Ph.D. Oklahoma State University, "Economic Analysis of Subsistence Agriculture in Garcia Rovira, Colombia."

Mark A. Lund, B.A. Augsburg College, 1969; Ph.D. Iowa State University, "Identifying, Developing, and Adopting Technologies Appropriate for Rural Development with Applications to Huari Province in Peru."

Ralph D. May, B.S.A. University of Arkansas, 1968; M.S. University of Arkansas, 1972; Ph.D. Purdue University, "A Systems Model of the Cattle Economy—A Guyana Application."

Lu Siong Ng, B.S. Iowa State University, 1969; Ph.D. Iowa State University, "An Income Distribution and Employment Consistency Model of the Philippines."

William C. Nickel, B.A. Rutgers University, 1967; M.S. Rutgers University, 1971; Ph.D. University of California, Berkeley, "Efficiency in Resource Use in Paddy-Intensive Southern Indian Agriculture."

Felix Nweke, B.S. University of Nigeria, 1967; Ph.D. Michigan State University, "A Systems Analysis and Simulation Study of the Nigerian Forestry Sector: Wood Consumption Component."

Soner Ogut, The Diploma of License (B.S.) University of Istanbul, 1965; M.S. University of Illinois, 1972; Ph.D. University of Illinois, "The Effects of Potential Resource Allocation Alternatives on Income and Employment for Three Rural Villages in Central Turkey."

Robert L. Pfeiffer, B.S. Kearney State College, 1956; M.S. University of Missouri, 1972; Ph.D. University of Missouri, "Factors Influencing Labor Force Migration in Missouri, 1960–1970."

Radzuan Bin Abdul Rahman, B.S. University of Malaysia, 1969; M.S. Cornell University, 1972; Ph.D. Cornell University, "The Economics of the Timber Industry in West Malaysia: A Case Study."

Raphael Shen, M.A. Berchmans College, 1965; M.A. Xavier College, 1967; M.A. Michigan State University, 1974, Ph.D. Michigan State University, "Narrowing Taiwan's Per Capita Farm/Nonfarm Income Gap via Increased Agricultural Production and Guaranteed Prices: Projections and Analysis, 1973–1984."

Paul Kelly Steidlmayer, B.A. Gonzaga University, 1965; M.A. Gonzaga University, 1966; Ph.D. Stanford University, "The Da Zhai Model in Chinese Agriculture: A Study of Policy, Its Implementation and Performance (1960–74)."

Fred Joseph Stewart, B.S. University of Montana, 1967; Ph.D. University of Kentucky, "Potential for Increased Net Incomes on Small Farms in Four Eastern Kentucky Counties."

Miguel Teubal, B.S. University of California, Berkeley, 1958; M.A. University of California, Berkeley, 1964; Ph.D. University of California, Berkeley, "Policy and Performance of Agriculture in Economic Development: The Case of Argentina."

Robert L. Thompson, B.S. Cornell University, 1967; M.S. Purdue University, 1969; Ph.D. Purdue University, 1974, "The Metaproduction Function for Brazilian Agriculture: An Analysis of Productivity and Other Aspects of Agricultural Growth."

Eric F. Tollens, B.S. Catholic University of Louvain, 1967; M.A. Michigan State University, 1970; Ph.D. Michigan State University, "An Economic Analysis of Cotton Production, Marketing and Processing in Northern Zaire."

Andres T. Vilas, B.S. Universidade Rural do Estado de Minas Gerais (Vicosa), 1965; M.S. Universidade Federal de Vicosa, U.F.V., 1971; Ph.D. Purdue University, "A Spatial Equilibrium Analysis of the Rice Economy in Brazil."

Jong Tack Yoo, B.A. Seoul National University, 1961; M.S. Montana State University, 1972; Ph.D. Michigan State University, "A Short and Long Run Analysis of the Korean Rural Demand for Food and Its Implications to Agricultural Policies."

Environmental Economics

Jeffrey V. Conopask, B.S. Purdue University, 1969; M.A. University of Toledo, 1971; Ph.D. Virginia Polytechnic Institute and State University, "An Ecologic-Economic Perspective for Coastal Zone Management."

Demitri Damianos, B.S. University of Rhode Island, 1971; M.S. Virginia Polytechnic Institute and State University, 1972; Ph.D. Virginia Polytechnic Institute and State University, "The Influence of Flood Hazards upon Residential Property Values."

Roger Maconick, B.A. Oxford University; M.A. Washington University; Ph.D. University of Wisconsin-Madison, "Optimal Allocation of a Renewable Resource: A Control Model of the Lake Superior Lake Trout Fishery."

James Paul Rathwell, B.S. Arizona State University, 1969; M.S. Oklahoma State University, 1972; Ph.D. Oklahoma State University, "Economic and Environmental Impact of Nitrogen Fertilizer Use."

Abdullah Ahmad Saleh, B.S. University of Pakistan, 1964; M.S. University of Missouri, 1970; Ph.D. Purdue University, 1974, "An Analysis of Consumer Food Expenditures and Consumption Waste."

James C. Wade, B.A. Abilene Christian College, 1967; M.A. University of Texas-Austin; Ph.D. Iowa State University, "Stream Sediment Movement, Water Quality and Agricultural Production: A Modeling Approach to Economic and Environmental Analysis."

Human Resource Development

Leon Elverne Abbas, B.S. Iowa State University, 1963; M.S. Montana State University, 1969; Ph.D. Oregon State University, "An Economic Analysis of Occupational Mobility: A Case Study of Oregon Commercial Fishermen."

Liu-Hsiung Chuang, B.A. National Taiwan University, 1961; M.A. National Taiwan University, 1965; M.S. Brigham Young University, 1968; Ph.D. Stanford University, "The Role of Human Capital in the Process of Economic Development: A Case Study of Japan."

Samuel T. Cooper, B.S., 1964; M.S. University of Missouri, 1965; Ph.D. University of Tennessee, "An Economic Analysis of the Training and Technology Manpower Training Program, Oak Ridge, Tennessee."

Labh Singh Hira, B.S. Punjab Agricultural University, India, 1969; M.S. Punjab Agricultural University, 1971; Ph.D. University of Missouri, "An Empirical Study of Advertised Retail Meat Prices in a Metropolitan Area."

Obituaries

Charles Lamar Anderson

Charles Lamar Anderson, associate professor, Food and Resource Economics Department, University of Florida, died on 1 January 1976 at the age of 48. He is survived by his wife Betty Jane of Lake Alfred, Florida, son John Charles Anderson of Lake Wales, Florida, and daughter Catherine Louise Hester of Auburndale, Florida.

Anderson was born at Largo, Florida, on 14 May 1927. He received his B.S. degree in animal science in 1949 and an M.S. degree in agricultural economics in 1969 at the University of Florida. At the time of his death, Anderson was serving as Extension Farm Management economist at the Agricultural Research and Education Center, Lake Alfred, Florida.

Charlie Anderson was a practical economist and extension educator. His varied background as a ranch hand, ranch manager, pilot, lawman, and county agent, prior to joining the Food and Resource Economics Department in Extension Farm Management, contributed to his success in working with growers and ranchers. He was a genuine person, liked and respected by all those he contacted. The statewide tribute that has been paid to Charlie Anderson is a fitting testimony to his success as an extension educator.

Durward Brewer

Durward Brewer, Department of Agricultural Economics, University of Missouri-Columbia, died on 17 November 1975 in DeQueen, Arkansas, leaving as his survivor his devoted wife, Margaret, now living at Wickes, Arkansas. Brewer had never completely recovered from lung surgery, which took place in early 1975.

Born on 28 August 1925 near Rogers, Arkansas, Brewer was raised on a general farm and carried away with him a set of agrarian values that provided the basis for his philosophy of life. During World War II, he served for three years as an infantryman with combat experience in the European Theater.

After returning from the war, Brewer enrolled in college. He attended the University of Arkansas, Southern State College, and Henderson State Teachers College and was awarded a B.S. degree from Oklahoma A&M University in 1952. He earned his M.S. degree from the same school in 1953. Brewer completed his Ph. D. degree at the University of Missouri in 1960.

Most of Brewer's early research dealt with livestock marketing. He is better known, however, for his work in economic development, water-based recreation, land use, and taxation. His courses in economic development and welfare economics were always filled with examples from the world, for Brewer was a pragmatic man. One of the activities he enjoyed most was teaching an advanced undergraduate-graduate course in rural real estate appraisal. He enjoyed the thrill of enterprise and the market.

The students and colleagues of Durward Brewer remember him as one who valued individual accomplishment and who demonstrated those values in his own life through his many talents ranging from his profession to music to jewelry design to handmade musical instruments. He was an unusual man and the world will be a little lonelier place without him.

Robert B. Donaldson

Robert B. Donaldson, retired chairman of Agricultural Economics Extension, The Pennsylvania State University, died on 9 December 1975 in State College. He was 70. He retired from the University in 1970 after thirty-four years of service.

He received the B.S. in 1927 and the M.S. in 1934, both from The Pennsylvania State University, Rising through the ranks, he became chairman of the Extension Agricultural Economics and Rural Sociology section in 1952 and had administrative responsibilities for Extension Farm Management and Rural Sociology projects.

A specialist in the development of fruit and vegetable procurement systems, Bob advised regional and national chain stores on the design of efficient assembly methods and wrote a book, *Profitable Roadside Marketing*, which has become a guide for direct marketers of farm products. In 1963, he was a member of a team of U.S. specialists assigned to develop ways of improving import-export relations with the European Economic Community and Common Market countries, from which came a publication, *Toward Maintaining and Expanding Markets in Western Europe for U.S. Farm Products*.

Bob was a member of Alpha Gamma Rho, Gamma Sigma Delta, Sigma Phi Epsilon, and the American Agricultural Economics Association.

William I. Myers

William I. Myers died at his farm home near Ithaca, New York, on 30 January 1976 at the age of 84. His

death terminated a long and distinguished career in education and public service.

Myers was born at Lowman, New York, in 1891. He received the B.S. degree at Cornell University in 1914 and the Ph.D. in 1918. He was appointed assistant professor of farm management at Cornell in 1918 and promoted to professor of farm finance in 1920. He became head of the Department of Agricultural Economics in 1938 and Dean of the College of Agriculture in 1943. He retired from Cornell in 1959.

As a young faculty member, Myers specialized in farm management, farm finance, and cooperative organization and management. He taught classes, conducted research, directed graduate students, and participated in extension activities. He was an inspiring teacher and counselor. His classes were always crowded. Graduate students were anxious to work under his guidance. He was a busy man who organized his time and worked long hours but was always available to the numerous students, associates, farmers, and public officials who sought his counsel. Myers understood people and could respond with friendly advice and a pat on the back or a kick in the pants depending on which he considered would be most appropriate. The Cornell faculty elected him to the Board of Trustees of the University in 1939.

Myers took a leave of absence from Cornell at the depth of the depression in early 1933 to go to Washington to work on the reorganization and expansion of the federal farm credit agencies. He became deputy governor and, later in the year, governor of the newly created Farm Credit Administration. In these capacities, he was the principal architect and, as governor, the top administrator during the revitalization, reorganization, and expansion of the national cooperative farm credit system. At the same time, he administered emergency credit made available to millions of desperate farmers. The existing Federal Land Banks, which like many banks in 1933 had great difficulty in acquiring funds to make new loans, were strengthened so they could expand their mortgage lending to farmers. Later, the short-term Production Credit system and the Banks for Cooperatives were created and added. For more than forty years, these institutions have provided the means through which billions of dollars were borrowed from the money market and loaned to farmers and cooperatives of farmers. Their wide use and strong financial condition bears witness to the soundness of their design and operation and to the efforts of many dedicated people, especially to those of Myers. Myers resigned as governor in 1938 and returned to Cornell.

Myers was interested in agriculture abroad as well as in the United States and was an early advocate of U.S. assistance. His primary concern was in strengthening research and educational institutions and in expanding opportunities for advanced training. He exerted influence in these directions as a member of the board of the Rockefeller Foundation. He was directly involved in the creation and financing of the Agricultural Development Council and served on its board for many years. While dean at Cornell, he initiated the working relationships between the University of the Philippines and Cornell.

Myers's counsel and advice were sought by scores of public and private organizations. Within New York State, he served on dozens of commissions and committees whose functions were to advise the governor, legislature, and other public officials on policy issues. At the national level, he served three presidents—Roosevelt, Truman, and Eisenhower. In addition to his work as governor of the Farm Credit Administration, he advised President Roosevelt on other issues. He served President Truman on his Famine Emergency Committee and the Committee on Foreign Aid. He was chairman of President Eisenhower's National Agricultural Advisory Commission.

In addition to serving on the boards of the Rockefeller Foundation and Agricultural Development Council, he served as trustee or director of numerous other organizations, including the General Education Board, American Institute of Cooperation, Twentieth Century Fund, Carnegie Institute of Washington, Eisenhower Exchange Fellowships, New York State Association for Crippled Children, Elmira College, and Vassar College. He was a member of the board of directors of many corporations including the Federal Reserve Bank of New York, Mutual Life Insurance Co. of New York, Continental Can Co., Insular Lumber Co., U.S. Industrial Chemicals, New York State Electric and Gas Corp., AVCO Corp., Smith-Corona Marchant, Marine Midland Corp., and Grand Union.

Myers received many honors. In 1938, the American Farm Bureau cited him for "distinguished service to agriculture." In 1949, his Cornell Class of 1914 awarded him its "Outstanding Achievement Award." He was secretary of the American Agricultural Economics Association in 1927–31, was president in 1934, and was elected a fellow in 1958.

Throughout his productive career, Bill Myers remained a man of the soil committed to the welfare of rural people. He purchased a farm near Ithaca, New York, early in his career and lived on it almost throughout. Working on his farm and in his garden provided relaxation and firsthand experience with farming and its problems.

Myers was married to the former Marguerite Troxell. He is survived by three daughters—Elizabeth Martin of Cincinnati, Ohio, and Marian Kira and Margaret McElwee both of Ithaca, New York.

Ermine Lawrence Potter

Ermine Lawrence (Dad) Potter, professor emeritus and the first head of the Department of Agricultural Economics at Oregon State University, died in November 1975 in Corvallis, Oregon, at the age of 91. He was known throughout the state of Oregon for his work in the livestock industry.

Born in Missouri, Potter was graduated with honors from Montana State College in 1906. He earned a B.S. in agriculture and an M.S. from Iowa State University. He later studied at Stanford University and the University of California.

Potter joined the staff at Oregon State University in 1908 as an instructor in animal husbandry. He was head of the Department of Animal Husbandry from 1913 to 1932, when he became head of the new Department of Agricultural Economics. He retired in 1950 but worked on a part-time basis until 1961, going to Thailand in 1952 to lay the groundwork for a contract between Kasetsart University and Oregon State University.

Potter, who wrote many Oregon State University Experiment Station bulletins, was instrumental in founding the Withycombe Club for animal science students at OSU. He was active in the Oregon 4-H Horse Club program, and this service was recognized in 1971 when he received the Oregon 4-H Distinguished Service Award.

Potter helped to organize the Oregon Cattleman's Association and the Pacific International Livestock Exposition. He was a pioneer scientist in improving range and livestock management.

He is survived by his wife, Norma.

Concepts in Agribusiness Management

RAY A. GOLDBERG, *George M. Moffett Professor of Agriculture and Business, Harvard Business School*

AGRIBUSINESS MANAGEMENT: TEXT AND CASES

A comprehensive graduate/professional-level introduction to agribusiness management . . . defines the concept of the agribusiness commodity system, shows how the system relates to the national and world economies, and identifies the organizations and institutions that participate in the system.

Summer, 1976 $15.00 (est.)

INTERNATIONAL AGRIBUSINESS COORDINATION

Considers, from a global perspective, wheat, soybean, rice, corn, beef, fruit, vegetable, and peanut commodity systems in a world systems approach to private and public decision making . . . encompasses market structure, coordinating institutions, public and private trade entities.

Summer, 1976 $15.00 (est.)

AGRIBUSINESS MANAGEMENT FOR DEVELOPING COUNTRIES

Latin America

The first of three regional commodity studies initiated by the U.S. Department of State to provide the capability and resources for training private and public agribusiness managers in the developing countries – a complete evaluation of Latin American fruit and vegetable agribusiness commodity structures.

Available $15.00

AGRIBUSINESS MANAGEMENT FOR DEVELOPING COUNTRIES

Southeast Asia

The second of three regional commodity studies funded by the U.S. State Department (Agency for International Development). Examines the development of corn production, processing, and distribution in Southeast Asia and the relation of the region's corn production to a world corn system.

Summer, 1976 $15.00 (est.)

FARMERS' COOPERATIVES AND FEDERAL INCOME TAXES

With Lee F. Schrader, Purdue University

Proposals for management strategies based on analysis of the relative benefits and disadvantages of cooperative tax status for the various participants in an agribusiness commodity system.

Available $13.50

ALSO PLANNED: MANAGERIAL STRATEGIES FOR COOPERATIVES
COOPERATIVE CORPORATE JOINT VENTURES

OTHER BALLINGER TITLES

ECONOMETRIC MODELS OF WORLD AGRICULTURAL COMMODITY MARKETS: Cocoa, Coffee, Tea, Wool, Cotton, Sugar, Wheat, Rice

F. Gerard Adams and Jere R. Behrman, University of Pennsylvania

New econometric models – structural in nature, relatively aggregative, and based on analysis of the dynamics of supply and demand response and of price determination for each of the markets.

Spring, 1976 $17.50 (est.)

AQUACULTURE FOR THE DEVELOPING COUNTRIES: A Feasibility Study

Frederick W. Bell and Ray E. Canterbery, Florida State University

Explores the possibility of aquaculture for increasing world protein supplies – based on research to encourage aquaculture technology among lesser developed nations.

Summer, 1976 $16.50 (est.)

THE COSTS OF CONGESTION: An Econometric Analysis of Wilderness Recreation

Charles J. Cicchetti, University of Wisconsin, and V. Kerry Smith, SUNY, Binghamton

The authors develop a general methodology for modeling the costs of congestion; problems of management and resource allocation in low density recreational lands.

Available $15.00

A Twentieth Century Fund Study

The New Economics of Growth

A Strategy for India and the Developing World

By JOHN W. MELLOR

A top specialist offers a bold new blueprint for alleviating poverty in the underdeveloped world by increasing the participation of the poor in the growth process. Pointing out the inadequacies of current development practices, Mr. Mellor sets forth a high-employment strategy centered on increased agricultural production. He tests his plan in the context of India—stronghold of the capital-intensive approach to development, which has so far produced disappointing rates of growth and little or no improvement in the economic condition of lower income groups. His book may well have a vital impact on the future welfare of the developing world. $11.50

Theory and Methods

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter to the editor, the author must state (*a*) that the material has not been published, and is not being published or being considered for publication elsewhere; (*b*) that the material in the manuscript, so far as the author knows, does not infringe upon other published material protected by copyright; and (*c*) that he or she is aware that each issue of the *Journal* is copyrighted, that submission of a manuscript to the *Journal* gives the AAEA the right to publish and to copyright the material, and that republication elsewhere at a later date is contingent upon written approval from the *Journal* editor. If the applicability of point (*a*) is unclear, the author should provide an explanation of the publication status of the manuscript.
2. **Author's identification.** In order to protect their anonymity in the review process, authors should avoid identifying themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on 8½-by-11-inch standard weight white paper with margins on all sides of at least 1¼ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of this *Journal*.
5. **Mathematical notation.** Use only essential mathematical notation; such notation is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable substitutes.
6. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type the footnotes, double-spaced, on a page following the article. The institutional paper number and acknowledgments, if any, should be placed at the beginning of the list of footnotes. Footnotes should be only explanatory and should not be used for citations or for directing the reader to a particular work. This information can be incorporated into the text itself.
7. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of the sentence, a parenthetical reference is unnecessary unless you need to cite page numbers or a date. A style sheet on references and citations is available upon request.
8. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
9. **Figures.** Prepare figures on heavy white paper or acetate sheeting using black India ink or paste-up types suitable for black and white reproduction by a photographic process. Typescript is not suitable.
10. **Three copies.** Send the typed original and two carbon copies or photocopies. All copies should be inspected for completeness and quality of reproduction.
11. **Review by colleagues.** Authors are strongly urged to have their manuscripts critically reviewed by their colleagues prior to submission.
12. **Abstract.** Instructions for the preparation of an abstract will be sent when the manuscript is accepted for publication.
13. **Page Charge.** All published contributions, with certain specific exemptions, are subject to a charge of $40 per printed page or fraction thereof. Exemptions are granted for book reviews, papers invited by the editor, the presidential address, the fellow's lecture, and those invited addresses and papers receiving explicit written exemption from the AAEA president. Authors who certify in writing that no financial support exists from an employer or granting agency to cover the page charge also will receive an exemption. Payment information and details on the financial exemption statement are provided with galley proofs. One hundred reprints (without covers) are provided if the charge is honored.

Objective

The AAEA seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy. The activities of the AAEA include:

—publishing the *American Journal of Agricultural Economics;*
—planning and conducting two annual meetings of the membership;
—sponsoring annual awards for outstanding extension programs, distinguished teaching, and outstanding research;
—recognizing outstanding agricultural economists through a fellows program;
—supporting a literature retrieval system in cooperation with the U.S. Department of Agriculture;
—publishing periodically a biographical directory of the AAEA's members;
—supporting an employment registry for agricultural economists in cooperation with the U.S. Department of Labor.

Membership and Subscriptions

Membership in the AAEA is open to individuals having a professional interest in agricultural economics. Dues, payable at the beginning of each calendar year, are as follows: regular members, $25, senior members, $12.50, and junior members, $12.50. Senior membership is open to persons, upon written request, who are sixty-five years of age or older and have retired from active professional work. Junior membership is for students and is limited to three years; students should use application forms available from and signed by the head of the department in which they are studying. Members receive this *Journal*.

The subscription rate for institutions and nonmembers is $35 per year. Individual issues of this *Journal* are $10.00.

Payment of membership dues, correspondence regarding subscriptions, orders for individual copies of the *Journal,* changes in address, or inquiries about the general affairs of the AAEA should be sent to John C. Redman, Secretary-Treasurer, American Agricultural Economics Association, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky, 40506.

A Bioeconomic Simulation Analysis of Regulating Groundwater Irrigation

Harry P. Mapp, Jr., and Vernon R. Eidman

This study develops a firm-level bioeconomic simulation model capable of stochastically determining yields for the major dryland and irrigated crops in the central basin of the Ogallala Formation as a function of soil moisture and atmospheric stress during critical stages of plant development. The model is used to evaluate three methods of regulating groundwater irrigation—no restriction, a quantity limitation, and a graduated tax per unit above the quantity limitation. Results differ for poor and adequate water situations but indicate the potential value of an educational program on timing of irrigation application to maximize net farm income.

Key words: bioeconomic simulation model, Ogallala, regulating groundwater irrigation.

The Ogallala Formation is a major unconsolidated aquifer providing irrigation water for much of the Great Plains. The formation extends from South Dakota to Texas, underlying parts of eastern Colorado, Nebraska, western Kansas, eastern New Mexico, the Oklahoma Panhandle, and the northern and southern high plains of Texas. The Arkansas River and Canadian River penetrate the formulation to bedrock, creating a separate hydrological subdivision known as the central basin of the Ogallala Formation. Water seepage into and from the aquifer is minimal. Thus, the central basin is essentially a closed container of water underlying a land area of approximately 17,500 square miles.

In recent years, increases in irrigated crop production and acre feet of water withdrawn from the central basin have been dramatic. With average annual recharge estimated to be only 0.27 million acre feet (Bekure), average annual overdraft currently exceeds 3 million acre feet. Continued overdraft leads inevitably to further declines in the water table and, other things being equal, to increases in pumping costs and reductions in the profitability of irrigated crop production. Eventually it will become uneconomical to pump water for irrigation purposes in some parts of the central basin. This implies resources once committed to irrigated production will revert to dryland farming. The adjustment from irrigated to dryland farming may result in serious primary and secondary reductions of income in the central basin. How severe the adjustments to the declining water table will be is determined in part by how fast the groundwater is depleted and in part by the actions taken to lessen the adverse effects of depletion. Consequently, the questions of concern to landowners, farm operators, businessmen, and policy makers alike are (*a*) what is the economic life of the water supply? (*b*) what will the economic adjustments in irrigated crop production entail? and (*c*) what can be done to mitigate the adverse effects of the declining water supply over time? The first two questions are addressed in an aggregate study by Bekure.[1] This study deals with the third.

Some policy makers and area leaders have suggested the appropriate method to mitigate the adverse effects is to meter wells and limit the amount of water use per year to the statu-

Harry P. Mapp, Jr., is an associate professor of agricultural economics at Oklahoma State University, Stillwater, and Vernon R. Eidman is a professor of agricultural and applied economics at the University of Minnesota, Minneapolis.

Journal Article No. J-3064 of the Oklahoma Agricultural Experiment Station. This research was conducted under Grant 14-01-0001-1539 from the Office of Water Resources Research and Oklahoma Agricultural Experiment Station Project No. 1358. The authors wish to thank Daryll E. Ray, Michael S. Salkin, and two anonymous reviewers of this *Journal* for their constructive comments on this manuscript.

[1] Drawing on earlier attempts by Kelso and Renshaw to evaluate groundwater as a stock resource and adapting methodology developed by Bellman and applied by Burt to groundwater reserves, Bekure projected the rate of groundwater withdrawal over the life of the aquifer and compared it to the rate of withdrawal that maximizes the net present value of the stock water resource. While his analysis indicates the projected rate of withdrawal will not exceed the rate maximizing the net present value, it does indicate significant adjustment to dryland farming will take place.

tory allocation of 1.5 acre feet per acre irrigated. This method of limiting water use would create some difficult planning problems for farmers in the area, given the variability of weather conditions.[2] The purpose of this study is to develop a bioeconomic model that can be used to evaluate the effect of alternative methods of water-use regulation at the firm level and to illustrate its use. The model is used to compute the firm-level effects of continued irrigation development on representative firms in two water-resource situations in the central basin.[3] In addition, the potential impact of regulating water use through a quantity limitation and a graduated tax per unit above the quantity limitation are evaluated. Variability in rainfall and evapotranspiration rates, which are of critical importance in determining crop yields, water pumped, and financial success in any year, are considered in the analysis to estimate the distribution of outcomes for each alternative simulated.

In the following section the problem of commonality of water use is discussed briefly and the rationale for the regulatory alternatives evaluated is presented.

Regulating Water Use

From a public viewpoint, maximization of long-run social benefits from the use of water represents the dominant goal of water-resource use (Timmons). This goal can be accomplished by efficient allocation of water among competing uses in present and future time periods. In the central basin of the Ogallala Formation, determination of the optimal allocation of the water resource at the firm level within and between production periods is complicated by problems of commonality and timing of water usage.

The problem of commonality of water-use leads to the divergence of private and social costs illustrated in figure 1 (Milliman).[4] The socially optimal allocation of water results when marginal social costs (*MSC*) are equated with marginal value product (*MVP*), resulting in use of *OA* acre feet of water. If the individual irrigator considers only marginal private costs (*MPC*) in the allocative process, water usage is expanded beyond the socially optimal level by amount *AD*.

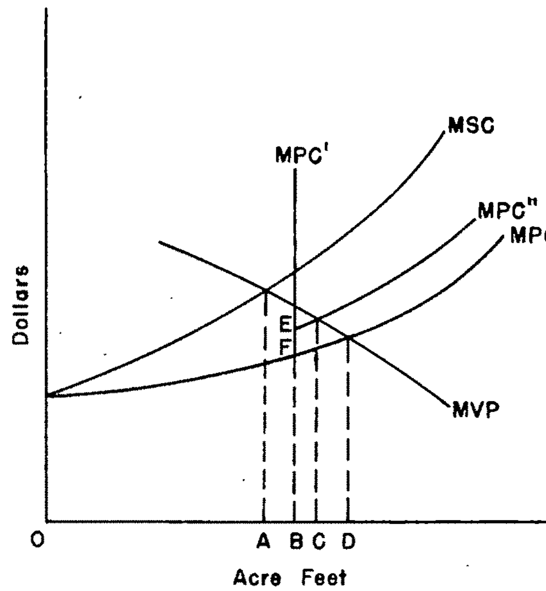

Figure 1. Effects of regulatory alternatives on the divergence of private and social costs

Several regulatory alternatives appear capable of more closely aligning marginal private and marginal social costs. For example, a quantity restriction equal to *OA* acre feet would result in a socially optimal allocation of water. A graduated tax equal to the difference between *MSC* and *MPC* for each acre foot of irrigation water pumped would likewise produce the socially optimal allocation.

This study is concerned with the firm-level impact of alternative measures society might take to align more closely marginal social and marginal private costs. No effort is made to define regulatory policies that equate private with social costs. The alternatives to no regulation evaluated in this study are selected because they appear to be more acceptable to irrigators, community leaders, and policy makers than regulatory methods that would

[2] The problem is one of deciding how many acres to irrigate given the uncertainty of water requirements. An irrigator that uses all of his allocation even ten days or two weeks before the end of the season may sustain large yield reductions, while irrigating fewer acres and "playing it safe" may result in the farmer foregoing a significant amount of income.

[3] The portion of the Central Ogallala Formation considered in this project includes part of two counties in southeastern Colorado, eight counties in southwestern Kansas, the three Panhandle counties of Oklahoma, and eight counties in the northern part of the Texas High Plains.

[4] A major cause of the divergence between private and social costs is the effect one irrigator may have on the pumping costs of other irrigators in the area. Removing water results in both increased pumping costs and reduced well yields for irrigators in the area of influence. Thus, one irrigator withdrawing large amounts of water relative to his neighbors' withdrawals may have a noticeable impact on their pumping costs resulting in the divergence of private and social costs illustrated for the individual in figure 1.

align more closely marginal private with marginal social costs.

At present, individual irrigators in the study area ignore the social costs of their actions. Irrigators are required to record water rights and space wells far enough apart to avoid obvious short-run conflicts but are operating in an environment relatively free of restrictions. This relative absence of water-use regulation is one alternative analyzed. Under this alternative, each farmer can withdraw the amount of water desired, limited only by the water-resource situation, pumping capacity, and the profitability of withdrawing water. The second alternative analyzed is a quantity limitation of 1.5 acre feet per acre of water rights. This method would require a significant reduction in pumping (approximately 25% below the current level) and has been suggested as an alternative by others dealing with the over-draft problem in the area (Kansas Water Resources Board).

In evaluating the effect of a tax on water use, the individual irrigator is allowed to pump without taxation until the quantity limitation is reached. Additional water is pumped only if the irrigator is willing to pay a tax of $0.50 per acre inch on each additional unit beyond the quantity limitation.

The three situations analyzed are depicted graphically in figure 1. Quantity *OD* represents the number of acre feet pumped by the individual who considers only private costs in the allocation decision. This "no restriction" situation is the first alternative simulated. Quantity *OB* represents the quantity of water pumped by an individual irrigator who equates MPC' and MVP under the quantity restriction and is the second alternative simulated. Imposing a per unit tax equal to, say, *EF* on each additional unit above *OB* would in effect force the irrigator to equate MPC'' and MVP, resulting in use of *OC* units of irrigation water. This is the third alternative simulated.[5]

Viewing the problem in a static setting (figure 1) is a useful manner to conceptualize the alternatives to be evaluated. However, an evaluation of the regulatory methods must consider the important dynamic elements of the problem. Within a year the uncertain weather and crop prices cause the expected *MVP* relationship to shift frequently between the time a farmer makes his planting decision and the time the final irrigation water is applied. Changes in the water table over time shift the marginal private cost curve. These dynamic aspects are incorporated into the model developed below.

Model Development

A firm-level bioeconomic simulation model is used as the basic tool in analyzing the three regulatory alternatives for two resource situations. Fundamental to the development of this model is the idea that timing of water application, rather than total amount applied, is of critical importance at the firm level. The operator observes the interaction of soil moisture and crop growth and development. The timing of an irrigation application and the quantity applied are determined by the operator on the basis of soil moisture and atmospheric stress conditions in relation to critical stages of plant development. His ability to respond to water-use restrictions depends upon his ability to reduce the quantity pumped but maintain crop yields by improving the timing of applications.

There is a growing literature documenting efforts to simulate bioeconomic systems. The work by Moore represents an early attempt by an economist to use simulation techniques to relate the incidence of moisture stress to crop yield under irrigated conditions. Moore argues that relative plant growth can be expressed as a function of available moisture depletion by inverting soil moisture release curves as they relate to available moisture depletion between field capacity and permanent wilting point. By using the moisture-release curve for a specific soil as an indicator of the relative growth rate of a plant grown on that soil, an index of

[5] The Oklahoma Water Resources Board has the power to order proper spacing of wells to insure an orderly withdrawal of water in relation to average annual recharge. It can also require metering of wells to record amounts pumped and can require persons to cease excessive withdrawals in reverse order of their water rights. It is empowered to restrict the rate of water use to one cubic foot of water per second for each seventy acres, or the equivalent thereof delivered on the land for a specified time in each year (Oklahoma Water Resources Board). By not indicating the intended length of "a specified time in each year," water use may be restricted to any amount desired by the Water Resources Board. Taxing water use does not fit within the current social or institutional structure of the study area. However, the graduated tax is evaluated in this study because it appears to be legally feasible and if administered appropriately would provide an economic incentive to conserve water. These by no means exhaust the regulatory possibilities. Additional restraints might include a lump sum tax on water use, a tax on each irrigation well, a limit on the number of wells per section or per farm, or a limit on well spacing. The possibility of importing water to sustain irrigated acreage could also be evaluated but was beyond the scope of this study. Time and resources did not permit evaluation of additional alternatives.

relative plant growth is derived. This index is multiplied by potential yield when water is not limited to obtain actual crop yield.

Flinn discusses models by Fleming and by Shaw that improve on Moore's assumptions by explicitly recognizing the interaction of soil moisture level and atmospheric demand for moisture on actual transpiration rates. These models relate plant growth on any day to the occurrence of moisture stress on that day. A moisture-stress day occurs whenever actual evapotranspiration falls below potential evapotranspiration.[6] Plant growth is assumed proportional to the number of stress days occurring during the growing season.

Implicit in these models is the assumption that the incidence and severity of stress alone reduces crop yields. Flinn argues both the incidence and severity of stress combine to determine crop yield and, in a recent model of corn development, relates growth in each time period to the incidence and severity of moisture stress in that period. Plant growth is assumed to decline in a linear fashion from the maximum rate of growth to no growth as the relative transpiration rate (ratio of actual to potential evapotranspiration) declines from 1 to 0.

The above models are designed to simulate soil moisture yield relationships for a single crop. Anderson and Maass present models to simulate the effects of temporary water shortages within the crop year on the final yield of several irrigated crops (Anderson, Anderson and Maass). Anderson and Maass divide the growing season into fourteen two-week periods, calculate quantities of water required by each crop during each period in typical irrigation sequences, and estimate the percentage reduction in crop yield assumed to occur if a specified irrigation is not applied. The model is applied to determine how best to allocate irrigation water among crops and farms participating in a water-distribution system under conditions of a limited supply of water. No attempt is made to model the soil-water– and atmospheric-stress–crop-yield relationships.

The model developed in this study determines yields on the basis of length and severity of both soil water and atmospheric stress in relation to critical stages of plant development for dryland and irrigated wheat, grain sorghum, and corn. The General Agricultural Firm Simulator developed by Hutton and Hinman is modified to simulate a representative farm for each resource situation. The major modification is the development of a production subset to simulate yields and irrigation water use in a stochastic framework.

The Production Subset

A basic assumption of the production subset is that under ideal soil water and atmospheric conditions some maximum potential yield may be achieved for each crop. In the event of plant stress, the amount of yield reduction depends upon the length and severity of soil-moisture stress and atmospheric stress in relation to the stage of plant development for each crop.[7] In implicit form, the yield reduction equation may be expressed as

$$YR_{ij} = f(SW_{ij}, AS_{ij}), \tag{1}$$

where YR = yield reduction, SW = soil-water level, AS = atmospheric stress, and i and j = the day and stage of plant development, respectively.

The level of soil water is a function of daily rainfall (RN_{ij}); evapotranspiration (EV_{ij}), which represents evaporative losses of moisture to plants and the atmospheric; and additions of moisture to the soil profile through irrigation applications (I_{ij}), or

$$SW_{ij} = g(RN_{ij}, EV_{ij}, I_{ij}). \tag{2}$$

Atmospheric demand for soil water is assumed to be a function of pan evaporation (PE_{ij}), or

$$AS_{ij} = h(PE_{ij}). \tag{3}$$

Thus, crop-yield reduction on day i of stage j is a function of the random variables rainfall, evapotranspiration, pan evaporation, and irrigation application rate.

The model requires daily estimates of soil water level and atmospheric demands upon the plants. A soil water balance is constructed, based on the findings and ideas pre-

[6] Potential evapotranspiration refers to the quantity of water that would be evaporated and transpired under adequate soil water conditions for a particular crop and stage of plant development. Measures of potential evapotranspiration are frequently related to pan evaporation. Actual evapotranspiration refers to the amount of soil water actually transpired and evaporated. For a given plant and stage of development, actual evapotranspiration is a function of potential evapotranspiration and soil water conditions.

[7] The terms moisture stress and atmospheric stress are used to describe plant stress. Plant stress occurs whenever demands upon the plant from the atmosphere exceed the ability of the plant's root system to draw water from the soil. Effects of inadequate soil moisture and severe atmospheric conditions are considered separately in this analysis because of the extremely arid conditions in the study area.

sented by Van Bavel, Thornthwaite, Thornthwaite and Mather, Holmes and Robinson, Denmead and Shaw, and Ligon, Benoit, and Elam, to provide daily soil-water levels adjusted to reflect additions due to rainfall and irrigation applications and subtractions due to evapotranspiration. Daily rainfall events are generated from discrete empirical probability distributions for each of fourteen two-week periods throughout the growing season. Daily pan evaporation values are generated from fourteen log-normal distributions of pan evaporation (Mapp).

Calculation of soil water on a daily basis permits consideration of the effects of soil water and atmospheric demands on crop yields on a daily basis. The combined effects of soil-water stress and atmospheric stress on yield reductions is assumed to be additive, due to lack of information regarding their interaction. Combining equations (1), (2), and (3), the yield reduction equation may be stated in explicit form as

$$(4) \qquad YR_{ij}^k = \theta_j^k SWD_{ij} + b_j^k(P_{ij} - P_a),$$

where YR_{ij}^k = yield reduction for day i, stage j, and crop k; θ_j^k = the coefficient reflecting yield reduction in units per day resulting from adverse soil water conditions; SWD_{ij} = soil water depletion in inches; b_j^k = the coefficient reflecting yield reduction in units per day due to severe atmospheric demands upon the plant; P_{ij} = pan evaporation in inches; and P_a = a critical pan evaporation level at or below which no yield reductions occur that are directly attributable to severe atmospheric conditions. The coefficients θ_j and b_j were estimated for three stages of plant development for grain sorghum, four stages for wheat, and five stages for corn.[8] The stages of development and soil water and atmospheric-stress coefficients for each crop are presented in table 1.

The production subset calculates the daily soil moisture balance for each crop block (field) included on the representative farm. The relation in equation (4) is used to calculate yield reductions for each day of the growing season for the crop produced on each crop block (field). The sum of the daily yield reductions is subtracted from the potential yield to obtain the yield for the crop block (field).

The production subset is quite flexible. It is used to calculate yields for dryland production as well as a variety of irrigation levels. The number and size of crop blocks (fields) can be adjusted to achieve the desired degree of realism concerning the precise time of irrigation and its effect on yield of the crops produced.

The Resource Situations

The resource situations were defined based on the saturated thickness of the Ogallala Formation. Saturated thickness is a critical determinant of both the quantity of water in storage and the yield of the aquifer in gallons per minute (GPM). The analysis was completed for

[8] Coefficients were synthesized and verified rather than estimated using sophisticated mathematical procedures. While it may be argued that mathematical estimation is preferable, lack of data for the study area eliminated this alternative. The coefficients, although probably not as accurate as implied by the use of two decimal places, nevertheless represent the best available estimates until more experimentation is performed and more data are available.

Table 1. Soil Water and Atmospheric Stress Coefficients for Grain Sorghum, Wheat, and Corn by Stages of Development

Grain Sorghum[a]	Preboot	Boot-Heading	Grain Filling
Soil water (θ_j)	0.30	2.04	1.27
Atmospheric (b_j)	1.30	1.65	1.50

Atmospheric (b_j)	0	1.10	1.20	1.50

Corn	Vegetable 1	Vegetable 2	Silking	Milk	Dough
Soil water (θ_j)	0.20	1.15	3.05	1.14	1.57
Atmospheric (b_j)	0.10	0.60	1.60	0.40	0.10

[a] The soil water stress coefficient of 0.30 for preboot stage of grain sorghum development denotes that as soil water approaches wilting point, yield reduction approaches 0.30 bushels per acre per day. The atmospheric stress coefficient of 1.30 indicates that under the most severe atmospheric conditions yield reduction approaches 1.30 bushels per acre per day.

each of two saturated thicknesses to obtain information on the effect of this factor on the analysis. Resource situation 1 has a saturated thickness of 100 feet representing the "poor water" situation within the study area. Resource situation 2, with saturated thicknesses averaging 325 feet, represents the "adequate water" situation in the study area. Each resource situation is characterized by a representative farm firm, and the effects of continued pumping on saturated thickness and well yield are simulated through time.

Surveys from seventy-eight randomly sampled farm operations were utilized to develop an organization for the representative farm (table 2). Assumptions concerning the machinery complement, overhead costs, labor requirements, prices, and irrigation equipment are given elsewhere (Mapp).

Irrigation Strategies and Behavioral Assumptions for Unrestricted Pumping

The irrigation operator is assumed to know the critical water-use periods for each crop and which of the several crops requiring water during a specific period has the highest use value for the irrigation water available. He is assumed to apply water during a specific period first to the crop that has the highest use value (marginal value product) for that unit of irrigation water. Once that crop has received an irrigation application, the crop or crop block having the highest marginal value product for the next unit of irrigation water receives the next irrigation application. The operator may switch crop priorities from one part of the growing season to another in response to changes in the value of irrigation water among crops.

To simulate the decision environment, the growing season is subdivided into five irrigation periods based on critical stages of plant development for grain sorghum, wheat, and corn. A crop calendar (table 3) shows the period when two or more crops are in direct competition for irrigation water and the irrigation priorities.

The decision maker bases the application of irrigation water upon the level of soil water. The decision to irrigate is made when the level of soil water falls below a critical level of available soil water (50% in this analysis). The

Table 3. Delineation of Critical Stages of Plant Development and Irrigation Priorities

	May	June	July	August	September
	1 7 15 23 31	6 13	2 16 18	4 9 24	1 15 22 30
Grain sorghum[a]	Preplant		Preboot	Boot-Heading	Grain-Filling
Wheat	Preboot Boot Flower Milk				Preplant
Corn[b]	Preplant Vegetative 1	Vegetative 2	Silking	Milk Dough	

Critical periods	May 1–15	May 16–June 5	June 6–Aug. 4	Aug. 5–Sept. 15	Sept. 16–30
Irrigation priorities[c]	G,W,C	W,C,G	C,G	G,C	G,W
Pumping days	14	20	56	39	14

[a] No stage name is given to grain sorghum between preplant irrigation applications and preboot stage. Moisture stress during this period has little effect if moisture is adequate during subsequent stages of development.
[b] Plant emergence occurs between May 1 and 7.
[c] Irrigation priorities G, W, and C represent grain sorghum, wheat, and corn, respectively. All of the crop listed first in a critical period is irrigated before the second- or third-priority crops.

irrigation priorities in table 3 indicate the order in which soil water values are checked. A complete discussion of the development of the crop calendar and irrigation strategies is presented in Mapp et al.

Three water-use alternatives are simulated. The "no policy" alternative follows the above procedure to allocate water from the one well with an initial capacity of 900 GPM. Irrigators in resource situation 1 face declining well yields over the twenty-year simulated time period. When the capacity of the system falls below 750 GPM in a given year, the irrigator is assumed to drill a new well at the end of that year. When the operator has three irrigation wells, his response to declining well yields is to reduce the number of irrigated acres. An irrigated crop block is converted to dryland in the year following receipt of net returns less than the expected net returns for the best dryland alternative.[9]

Behavioral Assumptions for the Quantity Limitation and Graduated Tax

Imposing either of the regulatory alternatives is expected to induce irrigation operators to adopt strategies that increase expected returns per acre inch of water applied. This is made operational by imposing maximum limits on the amount of water that will be applied on each crop in each of the five periods. Decisions on the application of irrigation water under the quantity limitation are similar to the decisions under unrestricted pumping except that the maximum limits are imposed.

The maximum limits by period are also imposed in simulating the irrigators' response to the graduated tax alternative. When the limit on tax-free water has been used (1.5 acre feet per acre), the irrigator is assumed to apply an additional irrigation only if the additional expected returns are greater than the sum of the variable pumping cost and the tax payment.

The unrestricted pumping alternative, a quantity limitation alternative, and graduated tax alternative are simulated over a twenty-year period and replicated fifteen times.[10] The results of these simulation runs are discussed in the following section.

Results

Amount of Water Pumped

The effects of the three water-use alternatives on the amount of water pumped are presented in table 4 for the two resource situations. Consider the values for resource situation 1 in the top one-half of the table. From year 1 through year 10, the mean value of total acre inches pumped under unrestricted pumping exceeds acre inches pumped under the quantity limitation of 1.5 acre feet per acre and graduated tax of $0.50 per acre inch above the quantity limitation. During the same period, the irrigator paying a graduated tax for each acre inch above the quantity limit finds it profitable to pump water in excess of the quantity limitation every year except two. A third irrigation well is usually added by year 10 under the unrestricted alternative, by year 11 under the graduated tax alternative, and by year 12 under the quantity limitation. This reflects the different rates of pumping under each alternative in early years of the simulated time period.

From year 12 to year 20, there is a complete change in the pattern of total acre inches pumped under the three water-use alternatives. Greater withdrawals in early periods under the unrestricted alternative reduce irrigation system capacity to such an extent that the lowest mean total acre inches pumped from year 12 through 20 is by the unrestricted irrigator. Water use under the graduated tax alternative is somewhat larger over the period than for the unrestricted alternative. The largest rate of water use during the period occurs under the quantity restriction in which

[9] The interrelationships among water-use policy, water-use rates, investment in irrigation equipment, and reduction in irrigated acreage create a rather complex decision environment. In this analysis, simulation of the response of irrigators to declining well yields is based on actions of good managers in the study area as observed by irrigation and farm management specialists familiar with the area.

[10] Each simulation run (replicate) covered a twenty-year simulated time period. A twenty-year period was selected based on the analysis of Bekure indicating the likelihood of economic exhaustion in some portions of the study area within twenty years. During each year of the simulation run, a set of daily rainfall and pan evaporation events were generated, crop yields were determined on the basis of soil water and atmospheric stress, crops were harvested and sold, decisions were made to replace fully depreciated machinery, taxes and family consumption expenditures were deducted, and the ending financial situation was calculated. Each replication traces the firm through an entirely different set of random weather events. Model validation received considerable attention. Coefficients developed for the crop response model were evaluated by agronomists, soil physicists, and agricultural engineers. The behavioral aspects of the model were developed in conjunction with farm management and irrigation specialists familiar with practice utilized by the better managers in the study area. Model validation is treated by Mapp et al. While many replications were utilized in validating the model, available resources limited the analysis to fifteen replications.

water is not depleted as rapidly in earlier years of the simulated time period as for the other two alternatives.

The figures in the bottom half of table 4 reflect total acre inches pumped for resource situation 2. The number of acre inches pumped under the unrestricted alternative exceeds total acre inches pumped under the graduated tax alternative by a wide margin. Water use in the graduated tax alternative also exceeds water use under the quantity restriction by a wide margin. In addition, there is considerably more variability in water use associated with the unrestricted alternative. As expected, of the three alternatives, the quantity restriction has the smallest variation in total acre inches pumped.

Relative Rates of Water Withdrawal

Table 4 also summarizes saturated thickness remaining at the end of the twenty-year simulation run. For resource situation 1, the mean values of feet of remaining saturated thickness are 35.84 for unrestricted pumping, 38.37 for quantity restriction, and 37.72 for graduated tax alternatives. Water is used at different rates for each alternative, but regardless of the alternative utilized the ending position is approximately the same. The individual farmer either completely returns to dryland farming or stabilizes at about eighty acres of irrigated grain sorghum and attempts to spread fixed costs of the irrigation system over forty to sixty-five acres of irrigated wheat during portions of the crop year not devoted to intensive summer irrigation of grain sorghum. From the standpoint of the underground water supply, each of the alternatives simulated leads to economic exhaustion within resource situation 1 in about twenty years, given the assumptions of the model.[11]

Table 4 also presents feet of remaining saturated thickness for each water-use alternative for resource situation 2. Mean levels of saturated thickness are 235.02, 251.81, and 245.61 for the unrestricted, quantity restriction, and graduated tax alternatives. The average feet decline in saturated thickness are 89.97, 73.19, and 79.39 for the three water-use alternatives, respectively.

[11] The Wilcoxon Matched Pairs, Signed Ranks Test (Siegel) was used to test each set of mean values of total acre inches pumped under the three institutional alternatives. These tests revealed no differences among the distributions at the 5% level of significance.

Note: The values in this table are based on fifteen replications. The values for each replication are reported by Mapp.

Net Farm Income

Mean values of net farm income for years 5, 10, 15, and 20 for each resource situation are presented in table 5. For resource situation 1, net farm income under the graduated tax alternative exceeds net farm income under the unrestricted pumping alternative during every year except year 5. Beginning with year 6, net farm income under the graduated tax alternative exceeds net farm income under unrestricted pumping by a wide margin. Several interrelated factors create this phenomenon. The unrestricted irrigator tends to operate his irrigation system at its maximum capacity. In responding to soil moisture levels throughout the growing season, the tendency is to attempt to maximize yields rather than profits. Thus, irrigation use is pushed beyond the most profitable level. Also, irrigators facing the graduated tax pump less water during earlier years, preserving more saturated thickness and an ability to achieve more timely irrigation in relation to plant needs during critical periods of development in later years. More timely applications lead to higher final crop yields for the same amount of irrigation water. Since pumping costs rise more slowly, net returns per acre and net farm income are higher.

Mean net farm income for resource situation 2 appears in the bottom half of table 5. The moderate increase in net farm income over time reflects gradual retirement of chattel and real estate debts and accumulation of cash. The level of farm income under the graduated tax alternative is only slightly less than under unrestricted pumping. Both unrestricted pumping and the graduated tax alternative have levels of net farm income that greatly exceed the level under the quantity restriction.[12]

Discounting Net Income Streams

The streams of net farm income are discounted to their present value at several interest rates. Present values of net farm income

[12] The Wilcoxon Matched Pairs, Signed Rank Test reveals a statistically significant difference between mean values of acre inches pumped and net farm income for the unrestricted pumping versus quantity limitation alternatives, unrestricted pumping versus graduated tax alternatives, and graduated tax versus quantity limitation alternatives.

for each regulatory alternative at 5% and 8% interest rates for resource situations 1 and 2 are presented in table 5.

Major implications of the analysis are not altered by consideration of the present values of alternative streams of income. For resource situation 1, the present value of net income is greatest for the graduated tax alternative. This finding is not surprising since net farm income under the graduated tax alternative exceeds net farm income under the unrestricted pumping alternative during every year but one. The present value of net farm income under unrestricted pumping exceeds that under the quantity limitation. Net farm income under unrestricted pumping greatly exceeds net farm income under a quantity restriction during early years of the simulated time period. During early years, the discount factor is small and discounted values of net farm income is large. It is only during year 10 and years 17, 18, 19, and 20 that net farm income under a quantity restriction slightly exceeds net farm income under unrestricted pumping. In late periods, the discount factor is large, and contributions to the present value of net farm income are small.

For resource situation 2, the present value of net farm income under unrestricted pumping exceeds present values under both graduated taxation and a quantity limitation. This result is expected since the level of net farm income under unrestricted pumping exceeds that under the graduated tax every year except year 1. Since the levels of net farm income remain homologous over time, the present values are nearly the same. Present values of net farm income under both unrestricted pumping and graduated taxation exceed the present value of net farm income under the quantity limitation. This finding is consistent with the significant differences found between distributions of net farm income under unrestricted pumping and graduated taxation when tested against the distribution under the quantity restriction.

Net Worth

A summary of ending net worth for the two resource situations in years 5, 10, 15, and 20 under unrestricted, quantity restriction, and graduated tax alternatives is presented in table 6. For resource situation 1, ending net worth is greatest under the graduated tax alternative followed by unrestricted pumping and the quantity limitation. However, for resource situation 2, unrestricted pumping results in the highest ending net worth followed by the graduated tax and the quantity limitation.

Summary and Implications

This study developed a firm-level bioeconomic simulation model capable of stochastically determining yields for the major dryland and irrigated crops of the study area as a function of soil moisture and atmospheric stress during critical stages of plant development. The model was used to simulate three alternative means of regulating water use in the central basin of the Ogallala Formation. A "no restriction" alternative, a limitation on the quantity of water pumped, and a graduated tax above the quantity limitation were simulated for poor and adequate water-resource situations.

Policy implications differ somewhat for the

two resource situations. In the poor water situation, economic exhaustion appears likely in about twenty years unless a policy limiting water use to much less than 1.5 acre feet per acre is adopted. Policy makers interested in conserving water may be indifferent as to whether pumping continues unrestricted or is reduced by applying a limitation. However, this analysis indicates the more rational water use under the graduated taxation alternative results in a significantly greater level of net farm income than under either unrestricted pumping or a quantity limitation. For this reason, the policy maker might prefer imposition of a graduated tax on water use.

Restriction of water use for resource situation 2 has a different impact and somewhat different policy implications. Unrestricted pumping results in the greatest water use and highest level of net farm income. The analysis indicates that the graduated tax alternative reduces water use significantly while maintaining a level of net farm income comparable to that under unrestricted pumping. Nevertheless, individual irrigators are expected to prefer unrestricted pumping.

The quantity limitation may seem preferable to policy makers because it reduces water-use rates by the largest amount, requires fewer changes in the legal framework, and is easier to administer. However, this alternative provides the lowest level of net farm income with the greatest relative variability.

The analysis from these two situations indicates that the taxation alternative is probably preferable from the individual irrigator's standpoint to the quantity limitation. If it is essential to have the taxation alternative limit water use to about the same level as the quantity restriction, the tax could be imposed at a somewhat lower level, say, 1.3 or 1.4 acre feet, to achieve the desired result. However, imposition of the graduated tax requires significant changes in the legal and institutional framework. These changes may be both difficult to enact and administer.

Additional work is needed to evaluate other strategies of allocating water under both quantity and taxation alternatives. However, the variability in pumping requirements under the unrestricted and taxing alternative suggests that it will be very difficult to devise an irrigation strategy under the quantity limitation having comparable returns to a taxing alternative that uses approximately the same amount of water.

Perhaps the clearest implication of the analysis is the need for an educational program on allocating irrigation water to maximize net farm income in both resource situations. The model discussed could be used to illustrate the advantages of following such rules on typical and/or actual farms. An educational program of this nature would be more palatable to individual operators in the area than either a quantity restriction or a graduated tax on water use.

A Dynamic Regional Model for Evaluating Resource Development Programs

Fu-Lai Tung, James A. MacMillan, and Charles F. Framingham

The purpose of the paper is to describe and demonstrate the usefulness of a dynamic regional economic model for evaluating resource development programs. The model results indicate that without development programs land may constrain livestock production after 1976. The growth in crop production is demand determined and will not exceed available land. A labor requirement of 15,400 man-years is projected for 1976 with 2,600 unutilized. Output and income distribution effects of drainage, training, and land-clearing development programs are assessed for the Interlake Area of Manitoba.

Key words: Canada, Manitoba, program evaluation, regional models.

A number of agricultural resource development programs have been designed in Canada to increase agricultural productivity and improve incomes of low income farmers in rural areas. These include programs under the Agricultural and Rural Development Act, 1961 (ARDA), the Fund for Rural Economic Development, 1966 (FRED), and the Small Farm Development Program, 1972 (SFDP). The various programs have unique elements representing alternative approaches to resolving rural development problems. Establishing the effectiveness of these various programs requires innovations in evaluation models similar to the innovations Byerlee and Halter suggest are needed for agricultural sector analysis.

The purpose of this paper is to describe and demonstrate the usefulness of a dynamic regional economic model for evaluating resource development programs. The present paper deals with specific agricultural programs rather than sectorial strategies. The programs alter the resource base available to agriculture and production techniques and consequently increase agricultural output. Changes in agricultural production in turn have impacts on the level of economic activity in the region as well as other regions. For a more detailed review of the various regional development programs in Canada, see MacMillan, and MacMillan, Framingham, and Tung.

To evaluate these programs, information is needed on the economic interrelations among various sectors of agriculture and between rural and urban areas of the regional economy in order to identify the impacts of agricultural resource development programs (Heady and Sonka). The paper is organized into three sections: (*a*) structure of the dynamic simulation model, (*b*) application of the model in evaluating resource development programs, and (*c*) policy implications.

Structure of the Dynamic Simulation Model

A number of impact studies concerning the Interlake economy using a static input-output framework have been made (MacMillan and Lu 1972, 1973; MacMillan, Lu, and Framingham; Douglas and MacMillan; Molgat and MacMillan). The stability of technical relationships within and between sectors over time has been questioned on both theoretical and empirical grounds by many researchers (Theil and Tilanus, Ozaki, Sevaldson, Tung). In fact, resource development programs are directed to changing production structure. Hence, any impact study concerning resource development programs using input-output analysis needs to adjust for changes in technical coefficients and resource constraints over time.

Fu-Lai Tung is a research associate and James A. MacMillan and Charles F. Framingham are professors in the Department of Agricultural Economics at the University of Manitoba, Canada.

Financial support of the research from the Canada Council is acknowledged, as well as comments from W. R. Maki, R. M. A. Loyns, J. Seldon, E. W. Somers, M. Yeh, anonymous reviewers, and *Journal* editors.

Under a dynamic system, first an induced consumption effect arises as the increased production yields a greater amount of regional personal income that leads to increased consumption of goods and services. Second, in order to produce additional goods generated from indirect and induced consumption effects, the producing sectors need to increase their capacity. This effect is termed the induced capacity effect.[1]

The model consists of seven submodels:[2] (*a*) final demand, (*b*) trading coefficients, (*c*) primary resources, labor and land, requirements coefficients, (*d*) capital requirements coefficients, (*e*) resource constraints, (*f*) gross output determinants, and (*g*) impact determinants. Regional economic development resulting from the forces included in the model is summarized by a set of economic indicators included in the impact determination submodel. The first set of economic indicators to be measured is realized gross output. This indicator shows the general business activity associated with and without resource development programs and is considered as an intermediate goal showing the need for resource development programs. The second set of economic indicators to be measured is directly related to the objectives of regional development programs such as area income, government revenue, and resource utilization rates. The quantitative impacts on these indicators derived from the model can be employed to assess regional development programs' achievements of specified targets in a given time period.

Final Demand Submodel

In the dynamic model, final demands are projected for two independent groups, government and other final demand sectors. A simple regression on time is employed to estimate federal and provincial government expenditure function (TFG_t):

$$TFG_t = \beta_t + \eta t. \tag{1}$$

Federal and provincial government expenditures for each target year are allocated to the seventeen producing sectors FG_{it} according to the vector of federal and provincial governments demand for regional goods and services (θ_{i0}) generated from 1968 government expenditure survey data (Hickling-Johnston Limited):

$$FG_{it} = \theta_{i0} TFG_t \text{ for } i = 1, \ldots, 17. \tag{2}$$

It is hypothesized that local government expenditures for the lth category in year t (TLG_{lt}) is determined by the community's population size in the year (TP_t) and previous local government expenditure of the lth category TLG_{t-1}:

$$TLG_{lt} = g_{lt} + \phi_{lt} TLG_{lt-1} + \rho_l TP_t. \tag{3}$$

The vector of local government demand for regional goods and services constructed for each category (T_{il}) from 1968 local government expenditure survey data is used to allocate the projected local government expenditures (LG_{it}) into the seventeen producing sectors:

$$LG_{it} = T_{il} TLG_{lt}. \tag{4}$$

The sum of LG_{it} and FG_{it} constitutes the total government expenditures on goods and services in the ith sector.

The relevant export markets in this study include the rest of Manitoba and Canada. The Manitoba growth rate of output r_i is used to project the export demand (ED_{it}) for the ith sector:

$$ED_{it} = ED_{i0}[1 + r_i]^T \text{ for } T = t - 1968 \text{ for all } i = 1, \ldots, 17. \tag{5}$$

Projection of the remaining components of final demand is also based on the Manitoba's average annual output growth rate:

$$INV_{it} = INV_{i0}[1 + r_i]^T \text{ for } T = t - 1968 \text{ for all } i = 1, \ldots, 17, \tag{6}$$

and

$$UD_{it} = UD_{i0}[1 + r_i]^T \text{ for } T = t - 1968 \text{ for all } i = 1, \ldots, 17, \tag{7}$$

where INV_{it} and UD_{it} = the net inventory

---

[1] Doeksen and Schreiner state that the induced capacity effect arises during the first and second years following the initial change in investment and eventually tapers off to 0 over a period of years. However, induced consumption and capacity effects due to productivity increases resulting from development programs occur continuously over the projection period.

[2] See Tung for a more detailed description of the model and data used. Input-output coefficients (α_{ij}) show direct requirements of local input purchases (x_{ij}) and import purchases (m_{ij}) per dollar of output, i.e., $\alpha_{ij} = (x_{ij} + m_{ij})/x_{\cdot j}$, where import purchases include both intermediate and final goods. The multiplier calculated from input-output coefficients gives the increase in local area production plus imports due to an exogenous change in final demand. In the model, trading coefficients ($t_{ij} = x_{ij}/x_{\cdot j}$) are calculated to permit calculation of multiplier effects excluding imports. In the small area economy due to the magnitude of exports and imports, the underlying production theory assumptions associated with input-output coefficients are replaced with trade theory assumptions (MacMillan, Lu, and Framingham).

changes and the unallocated final demands for the ith sector in the year t, respectively.

Trading Coefficient Submodel

The nature of economies of scale for agricultural commodities in Canada can be found in the studies by Auer and by Yorgason and Spears. The generalized Cobb-Douglas type of production that permits variable returns to scale (Klein, Ozaki) is approximated in the model. Each farm size class, in terms of acreage, forms a production unit in each agricultural sector. Let FN_{jnt} be the farm numbers for the nth size class for the jth sector in the tth period. Given the assumption that the relation between imports for intermediate input and for final demand associated with each farm size class is constant, the trading coefficient for each sector in a given period (a_{ijt}) is represented by

$$(8)\quad a_{ijt} = \frac{\sum_{n=1}^{3}(AX_{jnt}FN_{jnt})}{\sum_{i=1}^{26}\sum_{n=1}^{3}(AX_{jnt}FN_{jnt})} = \frac{TX_{ijt}}{TX._{jt}}$$

for $j = 1, 2$, and $i = 1, \ldots, 26$,

where TX_{ijt} = input purchased from sector i by sector j in year t (i.e., the sum of total input i for each size class), $TX._{jt}$ = total inputs purchased by sector j in year t (i.e., the sum of total inputs of each size class, which is equal to total output from all production units), and AX_{jnt} = average per farm purchasing pattern for the nth size class in the jth agricultural sector. If changes in the distribution of farm numbers by size class and a more general form of input purchasing patterns for each size class are known, changes in trading coefficients for agricultural sectors over time can be estimated by equation (8). Mathematically, the procedures are represented by the following equations for sales to nonagricultural sectors:

$$(9)\quad TX_{ijt} = \sum_{n=1}^{3} AX_{jnt}FN_{jnt}$$

for $i = 1, 2$, and $j = 3, \ldots, 24$,

$$(10)\quad a_{ijt} = \frac{TX_{ijt}}{\sum_{i=1}^{2}TX_{ijt} + \sum_{i=3}^{26}X_{ij}}$$

for $i = 1, 2$, and $j = 3, \ldots, 17$,

and

$$(11)\quad a_{ijt} = \frac{TX_{ijt}}{TX._{jt}}$$

for $i = 1, 2$, and $j = 3, \ldots, 17$,

where TX_{ijt} = the estimated sales from the agricultural sector ($i = 1, 2$) to the jth sector in year t. A modified Markov process emphasizing migration relationships is specified by MacMillan, Tung, and Tulloch. It is used to project farm numbers by gross receipt class (FR_{ft}) using the transitional probability matrix (U'_{fm}):

$$(12)\quad FR_{ft} = U'_{fm}FR_{ft-1} \text{ for } f = 1, \ldots, 7.$$

Farm numbers are then allocated to the nth size class for the ith sector (FN_{int}):

$$(13)\quad FN_{int} = V_{ifn}FR_{ft} \text{ for } i = 1, 2,\ n = 1, 2, 3, \text{ and } f = 1, \ldots, 7,$$

where V_{ifn} = the coefficients of the number of farms for the fth gross receipt class in the nth acreage class in sector i. Given the estimate of FN_{int}, the trading coefficients are adjusted to the target years according to equations (10) and (11).

Primary Resource Coefficients Submodel

A primary resources (labor and land) requirement coefficient matrix Z_t (with elements z_{jrt}) is estimated for the initial year by the level of primary resources required by a sector to produce one unit of output. Factor productivity tends to change over time mainly due to continuous shifts in the economies of scale and continuous changes in the combination of factor inputs in production. The primary resource input requirement coefficients (z_{jrt}) are estimated as

$$(14)\quad z_{jrt} = \sum_{n=1}^{3}(fz_{jnr}FN_{jnt})$$

for $j = 1, 2$, and $r = 1, 2$,

where fz_{jnr} = the rth primary input coefficient of the nth farm size class (plant-scale) for sector j, and FN_{jnt} = farm numbers by size class. The primary input requirement coefficients (tz_{jrt}) are adjusted further by

$$(15)\quad tz_{jrt} = z_{jrt}/(1 + \Delta AP_{jr})^t$$

for $r = 1, 2$, and $j = 1, \ldots, 17$.

The growth rate of the rth primary input's

average productivity for the jth sector in year t (ΔAP_{jt}) is estimated from historical data.

Capital Coefficients Submodel

The dynamic input-output system can be extended to incorporate a replacement capital coefficient matrix as was done by Miernyk et al. To obtain the dynamic system, the final demand (FD_t) is reduced by the amount of capital investment needed to generate enough capacity to meet the realized gross output (RX_t). The explicit consideration of the capacity generating process is introduced into the input-output system by means of the B matrix for expansion of fixed capital coefficients and by the D matrix of replacement fixed capital coefficients. An element of B (b_{ij}) is defined as the purchase of expansionary capital (NI_{ij}) goods from sector i by sector j per unit increase in capacity (ΔCK_j) in sector j:

$$(16) \qquad b_{ij} = NI_{ij}/\Delta CK_j.$$

To complete the dynamic input-output system, the elements of the D matrix (d_{ij}) are defined as the purchase of replacement capital (RI_{ij}) goods from sector i by sector j in order to maintain a constant level of capacity (CK_{j0}) in sector j:

$$(17) \qquad d_{ij} = RI_{ij}/CK_{j0}.$$

The ΔCK_j and CK_{j0} must be determined a priori to estimate b_{ij} and d_{ij}, but capacity is difficult to measure since it is a vague concept. In the present study input utilization rates, the ratios of actual to potential input use, are estimated and compared. The factor that has the highest utilization rate is selected as the key factor in determining capacity for empirical estimation. The capacity for the jth sector (CK_{jt}) is obtained by

$$(18) \quad CK_{jt} = RX_{jt}/(EA_{jt}/EP_{jt}) \qquad \text{for } j = 1, \ldots, 17,$$

where RX_{jt} = the actual realized output of the jth sector in year t, and EA_{jt}/EP_{jt} = the ratio of actual to potential input use for the jth sector in year t. The increase in capacity (ΔCK_j) for sector j is then estimated by

$$(19) \quad \Delta CK_{jt} = CK_{jt} - CK_{jt-1} \qquad \text{for } j = 1, \ldots, 17.$$

For the initial year, CK_{jt-1} is estimated on the basis of 1968 utilization rates and the Manitoba growth in gross output by sector. Given the estimates of CK_{jt} and ΔCK_{jt}, equations (16) and (17) are used to determine the B and D matrices for dynamic input-output simulation.

Primary Resource Constraints Submodel

The resource constraints to be considered in the conceptual analysis should include labor, land, and capital for all sectors. The land constraint is applied only to agricultural sectors, and capital is assumed not to be a constraining factor.

The following procedures are employed to estimate future land available for agricultural production without land clearing programs. For each target year,

$$(20) \qquad LA_t = LA_{t-1} - SL_t + UL_t,$$

$$(21) \qquad SL_t = 0.1\, SL_{t-1},$$

and

$$(22) \qquad UL_t = \sigma + \pi t,$$

where LA_t = total land available for agricultural use without resource development program for year t, SL_t = amount of agricultural land converted to urban and public use in year t, and UL_t = land cleared without resource development programs, representing the amount of semiagricultural land converted to agricultural land without resource development programs. Letting UL^*_t be the increased land under the resource development programs in the tth target year, the total land available for agriculture with resource development programs (LA^*_t) becomes

$$(23) \quad LA^*_t = LA^*_{t-1} - SL_t + UL_t + UL^*_t.$$

Estimates of labor constraints for each target year are based on the demographic model of Maki, Framingham, and Sandell. The area's population size is derived from a base period to establish an estimate of a future population. The labor force is then derived from the ratio of projected population to labor force.[3]

Gross Output Determination

The basic balance equation of the dynamic input-output system is

[3] The Manitoba participation rates (labor force divided by population over 15) projected by Maki, Framingham, and Sandell increase from 0.772 for males and 0.361 for females in 1971 to 0.777 for males and 0.401 for females in 1976. The total population for the Interlake area is projected to decrease from 50,698 in 1971 to 48,311 in 1976.

$$(24)\quad FX_i - \sum_{j=1}^{17} FX_{ij} - \sum_{j=1}^{17} NI_{ij} - \sum_{j=1}^{17} RI_{ij} = FD_i - ID_i,$$

where FX_i = gross output consistent with final demand for sector i, FX_{ij} = total current input requirement by sector j purchased from sector i, NI_{ij} = fixed capital required by sector j purchased from sector i for expansion of capacity, RI_{ij} = fixed capital required by sector j purchased from sector i for replacement purposes to maintain the same level of capacity, and $FD_i - ID_i$ = the final demand with investment (ID_i) removed.

Letting A_t be the trading coefficient matrix for year t, B_t be the expansion capital coefficient matrix, and D_t be the replacement capital coefficient matrix, the dynamic input-output system in matrix form becomes

$$(25)\quad FX_t - A_tFX_t - B_t\Delta CK_t - D_tCK_t = FD_t - ID_t,$$

where ΔCK_t = change in capacity, and CK_t = capacity level at year t.

Unfortunately, the dynamic input-output system of equation (25) is not operational because ΔCK_t and CK_t are unknown. One must assume that there is a constant relation between the capacity and gross output for each sector. Thus, the ratios of capacity to gross output (FX_t) are the elements of the diagonal matrix D^* and the ratios of changes in capacity to gross output are the elements of the diagonal matrix B^*. The relations between CK_t and FX_t and ΔCK_t and FX_t are

$$(26)\quad CK_t = D^*FX_t,$$

and

$$(27)\quad \Delta CK_t = B^*FX_t.$$

The operational dynamic input-output system derived from substituting equations (26) and (27) into equation (25) becomes

$$(28)\quad FX_t - A_tFX_t - BB^*FX_t - DD^*FX_t = FD_t - ID_t.$$

Induced consumption effects through consumption-income relations stimulate the regional economy and result in an "induced accelerator" relationship. The complete dynamic system is

$$(29)\quad FX_t - A^*_tFX_t - BB^*FX_t - DD^*FX_t = FD_t,$$

where A^*_t = a matrix of trading coefficients and average propensity to consume by sector, and FD_t = final demand vector excluding household and investment sectors. Gross output by sector consistent with final demand is determined by solving

$$(30)\quad FX_t = (I - A^*_t - BB^* - DD^*)^{-1} FD_t.$$

Maximum output by sector (MX_t) consistent with resource constraints is

$$(31)\quad MX_{irt} = ZR_{rt}\frac{1}{tz_{irt}}\frac{FX_{it}}{\sum_{i=1}^{17} FX_{it}}$$

$$\text{for } i = 1, 2 \text{ for } r = 1, \text{ and } i = 1, \ldots, 17 \text{ for } r = 2,$$

where MX_{irt} = maximum output consistent with the rth primary resource constraint for the ith sector, ZR_{rt} = rth primary resource available for production, tz_{irt} = rth primary resource requirement coefficient for the ith sector in year t (see equation (15)), and $\sum_{i=1}^{17} FX_{it}$ = summation of output for the ith sector consistent with final demand obtained by solving equation (30).

Input-output analysis provides estimates of changes in output associated with a change in demand. Equation (31) can be used to calculate the maximum level of output consistent with available resources. This effectively permits output constraints based on resource scarcity, an issue neglected in standard input-output analysis. For example, the maximum livestock production (MX_{11t}) consistent with the land constraint is determined by total available agricultural land (ZR_{1t}), the land requirement per \$1,000 agricultural livestock output (tz_{11t}), and the ratio of gross output of livestock (FX_{1t}) to the total gross output of livestock and crop sectors $\left(\sum_{i=1}^{2} FX_t\right)$. The 1968 level of the requirement (Z_{iro}) for land and labor in the livestock sector are 0.05 acres and 0.44 man-years per \$1,000 output, respectively. Livestock was 71% of total agricultural output. The calculation constrains the relative use of land by livestock to be proportional to the share of agricultural output.

A similar procedure is used to estimate labor constraints for all sectors. In this case, the allocation of estimated total labor force is based on $FX_{it}/\sum_{i=1}^{17} FX_{it}$.

After the maximum output consistent with each primary resource input is determined, the maximum output of agricultural sectors (MX^*_{it}) is determined by

$$(32)\quad MX^*_{it} = \min\,[MX_{i1t}, MX_{i2t}]\ \text{for } i = 1, 2,$$

and of nonagricultural sectors is determined by

$$(33)\quad MX^*_{it} = MX_{i2t}\ \text{for } i = 3, \ldots, 17.$$

Realized gross output for each sector (RX_{it}) is then determined by comparing the estimates of gross output consistent with final demand to resource constrained output by sector:

$$(34)\qquad RX_{it} = MX^*_{it}\ \text{if } FX_{it} > MX^*_{it},$$

or

$$(35)\qquad RX_{it} = FX_{it}\ \text{if } FX_{it} < MX^*_{it}.$$

Realized gross output limited by resource constraints is referred to as supply-determined growth. On the other hand, if the realized gross output of a sector is determined by the estimates of gross output consistent with final demand then growth is demand determined. For elaboration of supply or demand-determined growth models, see Cornwall. An anonymous reviewer pointed out that, if a specific sector's output is limited (effectively) by a resource constraint, checks should be made to ensure that other "demand-determined" sector input requirements are met. In such a situation the import coefficient for the "demand-determined" sector would have to be increased, resulting in a decrease in the sector multiplier. Such a situation did not occur in the present study.

Application of the Simulation Model in Evaluating Resource Development Programs

A framework for measuring impacts of resource development programs was outlined by Barnard, MacMillan, and Maki prior to the initiation of the FRED evaluation research. FRED program managers commissioned and supported several special studies including benefit-cost analyses of manpower, drainage, and land-clearing programs. The benefit-cost analyses provided the data for sectorial allocations of program and client expenditures, the time path and magnitude of productivity benefits of the programs, and the income class designation of clients receiving benefits.

The first run of the simulation model determines the values of economic development indicators without resource development programs. The second run incorporates resource development programs into the system in determining the values of economic development indicators. In this run, the direct effects of resource development programs are incorporated in the final demand vectors. The difference between the two runs measures the combined impact of the three agricultural resources development programs on development indicators (figure 1).

A comparison of results with historical observations shows consistent projections of investment expenditures required to meet forecasted levels of output, as compared with historical observations of the capital output ratios for the agricultural sectors and factor input utilization rates due to the structural changes in the agricultural sectors, measured by an increase in the number of large farms and a decrease in the number of small farms. The forecasted factor input requirement coefficients and the trading coefficients consistent with the concept of productive capacity limitation by farm size class are very close to the observed coefficients. Economic development indicators (table 1) are simulated to permit comparison with 1976 census data when available. None of the projections exceed a deviation of 13% compared with the 1971 historical observations. The overestimation of agricultural gross output as well as farm income for 1971 may be due to the poor weather conditions in 1971.

The FRED plan allocates $85 million over the 1967–77 period to programs including manpower retraining, education, fisheries adjustment, the construction of highway and recreational facilities, drainage improvement, and land-clearing programs. Special studies of fisheries and recreation are in progress. Studies of highways, education, housing, drainage, land clearing, and manpower have been completed, but only the studies of drainage, land clearing, and farm management training have been incorporated into the dynamic simulation model.

The objectives of the drainage program ($7 million) are to increase agricultural production by increasing the quantity and quality of agricultural land. Net income associated with additional acres of crops and improved pasture existing after drainage was estimated by Norton and MacMillan (1970, 1972) to have a

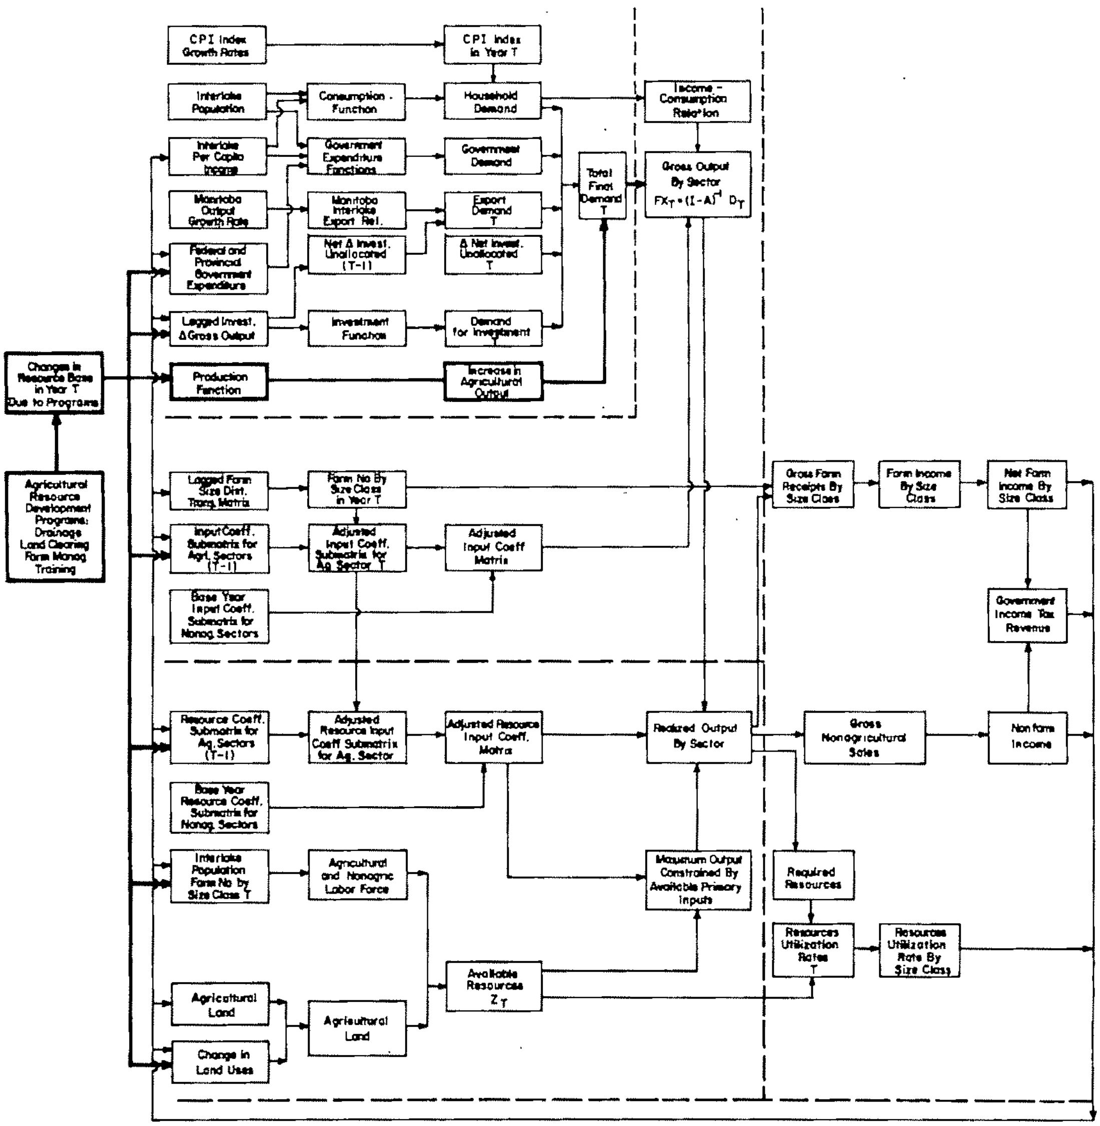

Figure 1. A diagrammatic presentation of the modified simulation procedures. The heavy solid line indicates the second step of the simulation procedures in which the effects of agricultural resource development programs are indicated in the related stages of the simulation procedure. The light solid line presents the first step of the simulation procedures.

present value of $3 million in relation to $1 million costs. The largest share of the total benefits was received by large farmers.[4]

The drainage program converts unarable land to arable land for agricultural production. Both quantity and quality of agricultural land are expected to increase through the drainage program, increasing agricultural output. The direct effects associated with the program include three aspects. First, the drainage construction expenditure can be considered as autonomous expenditures to the area economy. Thus, it will have a direct effect of increasing the area's output for the related sectors through the additional demand for goods and services resulting from drainage expenditure. When the program is terminated, the direct effect associated with drainage construction expenditure is also terminated. Second, the reclaimed land resulting from the drainage system leads to increased agricultural production

[4] The distribution of discounted drainage benefits per farm by 1969 gross receipts class estimated by Norton and MacMillan (1972, p. 51) is: $1,166 (< $2,500), $2,960 ($2,500–$4,999), $3,806 ($5,000–$9,999), and $18,194 (> $10,000). In total, 64% of the watershed income effect is estimated to be received by the 20% of the farmers in the over $10,000 receipts class in the watershed.

Table 1. Comparison of Goal Variables between Historical Observations and Model Results for the Interlake Area

Selected Economic Development Indicators	1971 Historical Observations	1971 Projection	1971 Impacts[a]	1971 Total	Difference between Historical Observations and Projection, 1971 (%)	1976 Projection	1976 Impacts[a]	1976 Total

Note: The full detail on derivation of historical series, comparison between alternative projections, and impact results can be found in Tung. The historical observations are in many cases estimates. For example, the man-years in agriculture are based on 1968 survey results believed to be more accurate than census farm numbers that apparently undercount the number of small farms.

[a] Total impacts of drainage, land clearing, and farm management training programs.

through a reclamation effect, a flooding effect, and a productivity effect. This part of the direct effect associated with the drainage program accumulates over the implementation period since the drainage systems are designed to be completed in different time periods. Third, there is an induced farm household consumption effect associated with the drainage program through increases in net farm income and program expenditure.

The land-clearing and demonstration program is designed to stimulate expansion of cultivated acreage in order to increase agricultural production and farm income in the area. Under the FRED agreement, an incentive grant of $4 per acre is paid to farmers who clear bush on approved land. In addition to the $4 per acre grant to farmers, there are administrative expenditures including forage seed purchases, salaries paid, demonstration and rental fees, and purchases of equipment and office supplies associated with the land-clearing and demonstration program.

Additional expenditures associated with the program are incurred by farmers in contracting or purchasing equipment for clearing the land. A benefit-cost analysis from the farmer's point of view by Pareek indicated that the present value of receipts equals clearing costs after three years. Eighty percent of the farmers were cropping their cleared land three years after clearing. A large majority of participants were low income farmers.[5]

The farm management training program establishes contracts with farmers for specific five-month courses. This special program was initiated in the Interlake in 1968 and has been extended to Manitoba and other provinces in Canada. Course sessions include instructions in soil and crop management, animal husbandry, farm accounting and business techniques, and applied science and mathematics. Selection of candidates for courses is made by local committees set up by area development boards. In general, selection is based on willingness to continue farming in future, preference for younger farmers with education greater than grade 7, and presence of a farm structure with the potential for sufficient size to ensure a long-term stable income. All farmers receive training allowances from the

[5] The percentage distribution of clients clearing land by 1970 gross receipts class estimated by Pareek is: 41% (0–$5,000), 30% ($5,001–$10,000), 17% ($10,000–$15,000), and 12% (> $15,001).

Canada Department of Manpower and Immigration. A benefit-cost analysis by MacMillan, Bernat, and Flagler indicated that farm management training has a payoff to clients greater than training industry, vocational courses in community colleges, and basic training for skills development. A majority of the farm management clients were low income farmers.[6]

There are three aspects of direct effects associated with the improvement of management skills of farmers by the management training programs: direct effects associated with the actual program expenditure, direct effects associated with increases in production in the farm sectors, and direct effects associated with increased farm household consumption purchases due to increases in net farm income. Moreover, the direct effects accumulate with increases in production and in farm household consumption.

The results (table 1) show effects of the 1967–73 program expenditures of $6.8 million on drainage, $0.7 million on land clearing, and $0.9 million on farm management in 1971 and 1976. The 1971 impacts include impacts of construction expenditures in 1971. Drainage construction was completed in 1973, so construction effects do not appear in 1976 impacts. To illustrate the effects of both construction and productivity increases in agriculture over the entire ten-year plan for particular programs, the annual average impact per $1 million program expenditure is calculated (table 2). Impacts are derived from the model results relative to six economic development indicators, including gross output, household income, income per farm, employment, government revenue, and income distribution. The indicators were selected in consultation with the FRED managers. Program impacts per $1 million are useful in assessing past impacts of programs and in consultations currently being conducted to determine future allocations of rural development expenditures in Canada. Measured by the impact on increasing gross output per $1 million of government expenditure, drainage and farm management impacts are similar. Drainage has the greatest impact on household income and income per farm. Farm management has the largest impact on employment. Land clearing has the greatest impact on government revenue and low income farms.

[6] The percentage distribution of farm management clients by 1968 gross receipts class estimated from data collected by MacMillan, Bernat, and Flagler is: 17% (0–$5,000), 70% ($5,001–$10,000), and 13% (> $10,000).

Policy Implications

The results can be used by policy makers to select programs consistent with priorities. If

Table 2. Average Annual Impact of Expenditures on Resource Development Programs, Interlake Area, 1969–77

Average Impacts on Selected Economic Indicators	Average Annual Impacts per $1 Million Expenditure		
	Drainage	Land Clearing	Farm Management
Realized gross output ($1,000)[a]	2,671	686	2,592
Agriculture	1,776	419	1,675
Nonagriculture	895	268	918
Household income ($1,000)	654	164	583
Agriculture	538	127	461
Nonagriculture	117	37	122
Income per farm ($)[b]	108	25	93
Employment (1,000 man-years)	149	49	195
Agriculture	123	41	168
Nonagriculture	26	8	27
Government revenue ($1,000)[c]	66	100	64
Agriculture	51	73	49
Nonagriculture	15	27	16
Impact on low income farms (%)[d]			
Distribution of benefits (%)	36	88	87

[a] The total nine-year impact of a $1 million program expenditure is $24 million in gross output for the drainage program (2.7 × 9).

[b] Income per farm is calculated by dividing the average annual agricultural sector income by the projected 1977 number of farms (4,793).

[c] Includes property, sales, and income taxes.

[d] Percentage of drainage benefits to farms under $10,000 gross receipts calculated by Norton and MacMillan (1972), of farmers participating in the land clearing program with gross receipts under $10,000 by Pareek, and of farm management trainees with gross receipts under $10,000 by MacMillan, Bernat, and Flagler.

income distribution is a top priority, land clearing and farm management training are "best." On the other hand, if output and income creation are a top priority, drainage is "best." The results could also be used to select a mix of programs. For example, farm management programs have impacts on output and income slightly below that of drainage but have a much greater effect on low income farms. The evaluation perspective focuses on providing information needed by policy makers without placing value judgements on the relative weights among indicators.

In the evaluation of resource development programs, the assessment of future growth in the regional economy without such development programs is required for a complete evaluation. The projection of the regional development process without development programs is not only critical for measuring the impacts of development programs but it also provides insights to policy makers in formulating appropriate development programs and planning. The dynamic simulation model indicates that without development programs land may constrain livestock production after 1976. Crop production will not be land constrained because the demand for crop production is projected to increase at a rate lower than livestock. The growth in livestock production is supply determined and programs are required to expand land supply or increase the livestock production capacity of land. Growth in crop production is demand determined and will not exceed the land resource available.[7]

The model results indicate that demand and supply of labor are clearly out of balance throughout the projection period. Without the three resource development programs, the problem of the high levels of unutilized labor in the Interlake will be extremely critical with 15.5% of the labor force unutilized in 1976. A labor requirement of 15,400 man-years is projected for 1976 with 2,600 unutilized. This is due to the fact that economic development that is motivated by technological changes in agriculture will continuously decrease labor required for agricultural production. The historical and projected distribution of farm numbers by gross receipts class is given in table 3. Man-years per $1,000 gross output is projected to decline from 0.138 for livestock and 0.181 for crops in 1968 to 0.08 for crops and 0.10 for livestock in 1976. Employment in nonagricultural sectors is expected to increase but not fast enough to accommodate the outmigration of unskilled farm labor. Complementary nonagricultural manpower training and education programs are needed to provide employment for the agricultural labor force to equip them with job skills for jobs in nonagricultural sectors within or outside the Interlake area.

The introduction of resource development programs can stimulate the Interlake area's economic development measured either in terms of income generation or job creation impacts, $10 million in income and 1,300 man-years of employment by 1976 (table 1). More specifically, each program introduced to the Interlake area provides positive impacts on all selected economic development indicators. The magnitude of the impacts per dollar expenditure on development indicators is not equal. A $1 million expenditure of public investment in the farm management training program would create more job opportunities than that of the other two programs, but it does not generate as much output or household income as the drainage program. The drainage program cannot solve the income distribution problem since 64% of increased income accrues to high income classes (see table 2).

The impacts of each resource development program on the selected economic development indicators are different from one time period to another. Detailed special studies of

Table 3. Historical and Projected Farm Numbers by Receipts Class

Gross Receipts Class	Historical 1971[a]	Projected 1976[b]
	Farm Nos.	
< $2,500	2,169	1,442
$2,500–$4,999	1,129	845
$5,000–$9,999	970	857
$10,000–$14,999	460	491
$15,000–$24,999	428	554
> $25,000	399	783
Total	5,564	4,972

[a] From Statistics Canada (1973).
[b] Projected using the model estimated by MacMillan, Tung, and Tulloch.

[7] Land cleared under the program over the period 1969–73 totaled 126,000 acres. Without the land-clearing program, 2 million acres were estimated to be available for agricultural production in 1976, which is equal to the land requirements estimated from the model. Land requirements are estimated from the model at 2.3 million acres in 1985, a short fall of 0.3 million acres. The annual growth rate projected for livestock output is 5.15% and for crops 3.45%, indicating the short fall is primarily due to livestock demand.

particular programs are required to provide productivity measures including benefit-cost ratios as well as link program expenditures to the regional economy. The simulation model highlights the accumulation of "pump priming" and productivity effects in contrast to the present value results of benefit-cost analysis.

Governments could be more effective in their pursuit of development targets by making objectives more specific in terms of the selected economic development indicators and analyzing the economic and structural changes caused by particular programs on an annual basis. Infrastructure expenditures in early years of a plan can provide jobs immediately in contrast to the several years required to generate jobs by increasing management skills of farmers.

A dynamic simulation model and data used in the study have several limitations including the scarcity of available data.[8] A serious limitation in the present model is the omission of adjustments for technological changes occurring within nonagricultural sectors. Capital constraints are not included in the model due to the complexity of capital flows among regions.

The omission of price changes in the model is a major limitation. The constant price ratio assumption used in the present model eliminates the substitution effect caused by relative price changes. In addition, the omission of price changes over time in the study prevents an analysis of the erosion in development impacts due to the decrease in purchasing power of program expenditures in later years of the plan due to inflation (see Johansen). The model cannot handle weather conditions affecting the agricultural input-output relations, and projections over the long term will show short-term variations due to weather fluctuations.

In summary, notwithstanding its limitations the dynamic simulation model described and applied in this study can be used to trace out the principal forces determining the pattern of regional development and in measuring the impacts of resource development programs on a regional economy.

[*Received September 1975; revision accepted March 1976.*]

[8] The estimates for the drainage by Norton and MacMillan, land clearing by Pareek, and farm management training impacts by MacMillan, Bernat, and Flagler were based on detailed sample surveys of fifty-one, ninety, and twenty-six farmers, respectively, and allocations to input-output sectors of the FRED budget were made in consultation with FRED administrators. Data on local government expenditures by sector were obtained by a detailed survey of local government expenditures by the Department of Agricultural Economics, University of Manitoba. The sectorial allocation of provincial and federal government expenditures was estimated from the business questionnaire results used in the estimation of the 1968 Interlake area transactions matrix. Allocations to particular expenditure functions were based on a 1968 survey of provincial and federal government expenditures conducted in 1969 by Hickling-Johnston Associates for the Manitoba Planning and Priorities Secretariat. The statistical properties of the household and business data used in constructing the 1968 transactions table are detailed in MacMillan, Lu, and Framingham. Investment rates were estimated from the Manitoba 1950–72 series obtained from Statistics Canada. Gross output rates of change were estimated from Manitoba Department of Finance data and the Commission on Targets for Economic Development. Agricultural and population data series were obtained from the Census of Canada (Statistics Canada 1950–72, 1973) and the Manitoba Department of Agriculture publications (1960–72).

Implications of Public School Finance Reform with Local Control

Fred C. White and Bill R. Miller

The nation's present interest in school finance reform concerns elimination of inequities in financing and improvement in the delivery of educational services. This paper examines one of the most popular school finance reform proposals that would allow the local school district to select an appropriate tax effort without directly linking quality of education to the district's wealth. Implementation of this reform proposal would result in a slight redistribution of income to poorer districts but would result in further inequities in quality of educational services.

Key words: school finance, taxation.

Local control of public schools has always been an important part of the educational system in the United States. With the exception of meeting some minimum requirements, local school districts have a great deal of flexibility in establishing their financial commitment. Differences in educational programs among school districts can, therefore, be attributed primarily to differences in fiscal capacity and commitment of residents to the support of education.

A major criticism of the present system of public school finance concerns the wide disparities with respect to tax burdens. There is a divergence among school districts with respect to tax rates and the level of expenditures per student generated by these tax rates. Wealth has been identified by various state courts as causing this problem because it was not distributed equally (Advisory Commission on Intergovernmental Relations 1973). A variety of financing plans for education are acceptable under the court rulings so long as quality of the educational program is not subject to the school district's wealth.

Selection of the appropriate instrument for public school finance reform requires clarification of educational goals. Reform proposals that appear widely acceptable maintain local control of tax rates without subjecting expenditure levels to local school district wealth. An alternative that meets these criteria—power equalization—has been proposed by Coons, Clune, and Sugarman. Under this plan, state aid is used so that at any level of tax effort every school district would receive the same level of revenue per student. If a district's tax base produces less revenue at a given rate than the permitted revenue level, the difference would be provided by the state general fund. Any excess over permitted levels would be contributed to this fund. Local school districts would establish their own tax rates for education, with expenditure levels determined by the selected tax rate and state average wealth.

Each district would select that tax rate appropriate to voter preferences within the district. This selection would also take into consideration factors associated with production including economies of scale in producing education and price of factor inputs. Thus the problem can be formulated in terms of supply and demand for education. However, previous discussions of power equalization have considered implications of tax reform while abstracting from relevant supply-demand considerations (Coons, Clune, and Sugarman; Treacy and Frueh; Weiss; Stubblebine and Teeples; Oakland). An exception to this statement is the work by Feldstein, who measured wealth neutrality by the elasticity of local school spending with respect to local per pupil wealth. To a large extent, power equalization must be evaluated on the basis of local communities' responses to the incentives it offers, which requires a knowledge of the pa-

rameters of communities' supply and demand functions for education.

Objectives

This article explores public school finance reform in Georgia. It first develops a method to quantify equilibrium levels of public school finance variables such as total current school expenditure minus transportation costs, state and federal aid to education, and supply and demand of local expenditures. Then the theoretical concept of supply and demand is structured as a set of simultaneous equations, which is estimated from cross-sectional data describing public school expenditures in Georgia counties. Finally, the estimated supply and demand relationships are applied to identify equilibrium levels of spending in local districts after removing inequalities due to differences in tax base.

Analytical Framework

In this research we specify public school services as a recognizable, although not measurable, output to the taxpayer but persist as others have in maintaining that the theory of supply and demand does apply. This approach follows Buchanan's theoretical analysis of supply and demand for public goods, as well as the empirical analyses of Barlow, McMahon, Ohls and Wales, and Borcherding and Deacon. Basic economic theory is shown to prevail in these empirical studies and others despite the explicit recognition that price and output of public services are not objectively measurable.

A principal difficulty in observing output quantities suitable for analysis is that the theory of supply and demand is traditionally discussed in terms of homogeneous units. Such units are clearly not produced by the school system. Students are part of the system input and their acquired skills and achievements are an obvious output, but the educational level of every student is different. A detailed discussion of the analytical framework explaining supply and demand for educational services follows.

Supply and Demand Variables

From a theoretical point of view, we use the commonly held assumption that a quantity index of educational service (Q) as demanded by the taxpayer is a function of prices of competitive goods and services, a price index of educational service (P), and the taxpayer's income. Similarly, Q is a function of the efficiency with which our schools are run, as this affects the cost of education, i.e., quantity demanded may not be supplied if costs are too high. There is a measurable total cost of obtaining these educational services, although neither the service nor its unit of quantity and price can be uniquely defined. Furthermore, from an empirical point of view there is not much hope that an empirically useful index of quantity or price will ever be defined. Nevertheless, the hypothesis that there are aggregate ratios of tax effort and educational cost to consumer income that contain within them the elemental forces of demand and supply is maintained. In this respect, we follow McMahon in his recent study of the expenditure-income ratio.

Perhaps importantly for economic analysis, measurable and observable costs of producing educational services are subject to modification not only by consumer behavior to tax structure on the demand side but also by changing costs and productivity on the supply side of the market. This interplay of market forces is observed as the local taxpayer pays the cost of consuming educational services through payment of taxes.

Any theory of demand for educational services that hopes to specify the behavior of consumers must explain the taxpayers' recognition of the interaction between expenditures and taxes. In this process the taxpaying consumer's economic behavior with respect to the case of consuming educational services is observed. Barlow is most explicit on this point. "Of all the major public expenditures in the United States, the expenditures of local public schools are perhaps the most responsive to the preferences of individual citizens" (p. 1028). Further evidence of the strength of this point of view is found in Bowen and Downs.

Simultaneous with the taxpayer's establishing and paying taxes, conditions are arising that seem to dictate the level of costs required for a given level of services. This is no different from the forces observed in any market. The supply of educational services, like the supply of any good, is related to factors affecting total costs: scale of plant, input mix within the school, and input prices. Borcherding and Deacon, for example, develop an explicit production function for education. Unlike other

markets, however, knowledge of the cost function is not sufficient to specify supply at the local level. Local costs of education and level of educational output may also vary among school systems because of differences in outside effort from state and federal sources. Thus, determination of local level of education is confounded, not only by the lack of measurable units of service, but also because the equilibrium level of local taxing must be found with respect to the level of local costs and outside government transfers. Inclusion of outside effort in the equilibrium process is consistent with common observation of the school economy, which demonstrates that the output of public goods would in general be too small without evolution of government systems to correct deficiencies. McMahon has also emphasized the exogenous character of outside aid. Thus, it appears that the equilibrium level of local tax contribution towards total costs of educational services is simultaneously determined by consumer demand for services, educational supply costs, and outside effort. This structure of relationships implies that local cost conditions cannot be brought into stable equilibrium with what local taxpayers are willing to pay until the exogenous level of outside effort is set by current policy of either simple grants or complex formula.[1] "The basic decision is the decision about how much to tax, which is constrained to a choice between taxing and borrowing, given state and federal aids" (McMahon, p. 245). We demonstrate a simultaneous equation model of these structural relationships below.

Operational Model

Specification of supply and demand for education requires at least two definitions. One, there must be an observable value that is subject to modification by consumer behavior in response to a measure of change in educational services. The hypothesis that property tax effort in Georgia has been responsive to the observed level of educational services is tested, although this effect is not as direct as previous studies have assumed. In brief, tax effort is a function of what taxpayers continually perceive as output from the school system. What is perceived as output and the quality of this output is then specified to be a function of the educational services provided by the school system. The second requirement is that the change in educational services must be an observable and measurable index. As we have already argued and as a number of studies suggest, total school expenditure meets this criteria; with modifications for achievement and efficiency of inputs, we use it as such in this study (Cohn, Riew).

A four-equation model is specified in which tax effort, achievement, total expenditures, and local expenditures are the four endogenous variables. The simplified structural form of the endogenous relationships appear as follows:

(1) Demand or Effort:
$$LTE = F(ACH;\ X_1 - X_5),$$

(2) Quality of Output:
$$ACH = F(EXP;\ X_6 - X_8),$$

(3) Cost of Output:
$$EXP = F(ACH;\ X_9 - X_{13}),$$

and

(4) Identity: $EXP = LX + OT$,

where LTE = local school tax effort for current expenditures per dollar of personal income, ACH = county average achievement score, EXP = total current expenditure per average daily attendance (ADA), LX = current expenditures per ADA financed from local sources, OT = county current expenditure per ADA funded from state and federal sources, and X_j = exogenous shifters of the functional relationships that will be described in detail later. This is a consistent model with regards to the endogenous relationships of stochastic variables. The following sections discuss these relationships in detail.

Demand as Tax Effort

Local tax effort reflects demand for services, including the willingness to supply the funds. The Advisory Commission on Intergovernmental Relations suggests that tax effort is effectively measured by the ratio of tax revenue to personal income (1962, 1973). Since school tax revenues are the observable local contribution to public education, we test the hypothesis that consumers as taxpayers are willing to increase local current expenditures per dollar of income whenever they observe increasing student achievement, other things being equal. Thus, demand expressed

[1] Under some aid formulas, the level of outside aid is not entirely exogenous but affected by the district's decisions on type of programs and financing.

as local tax effort is defined to be $LTE = (LC/CY)(100)$, where LC = local contributions for current expenditures (excluding transportation), and CY = county income. Thus, the numerator is total local contribution of current school expenditures, and the denominator is the county's total personal income.

Quality of Output

Kiesling has pointed out that it is a dangerous practice to use expenditure data as an index of change in educational services without an allowance for differences in quality. Kiesling also concludes that, "given the well-known problems in measuring public service outputs, it is surprising that test scores have not been more widely used by economists in education research" (p. 356). Test scores, or student achievement scores, are among the immediately recognizable results that taxpayers observe from the educational system. Even when test scores are not known, they are closely related to those things that taxpayers do observe, such as high school dropout rates, the number of students attending college, the initial job success, and the success in post-secondary schooling. Thus, in this research it is assumed that tax effort by taxpayers is jointly determined with the observed level of quality as measured by achievement. Other measures of quality are no doubt available, but achievement scores offer the advantage of being widely available and comparable to some degree. We hypothesize that local tax effort (LTE) will rise as achievement levels rise and that there is an endogenous relationship between achievement and the cost of educational services.

Cost of Output

Although previous research results aimed at identifying the relationship between student achievement and expenditures have been inconclusive (Coleman et al., Flanagan et al., Jencks et al.), the present analysis will explore the possibility of such a relationship. The logical assumption is, with other things being equal, higher quality output has a higher unit cost. Our estimates of total current expenditures per ADA are thus related to quality by including achievement in the equation for EXP; simultaneously, EXP is expected to affect achievement. Other important determinants of cost are then added to the equation as exogenous variables as an attempt to adjust for their effect and thereby isolate the expenditure-quality relationship.

Identity

The statistical model is closed by specifying that total expenditure per student (EXP) minus local expenditure per student (LX) equals outside effort per student (OT). Outside aid is determined by a formula (which may consider differences in cost as well as ability to pay) making the amount coming to a district exogenous to the district. After that, the district is left to itself to make LTE consistent with LX.

Exogenous Variables

The statistical model allows the number of students measured as ADA to be an exogenous variable. One of the causes of imbalance in local school system financing is economies and diseconomies of size in student enrollment that are exogenous or beyond control of the system. The number of students has a significant effect on educational costs per student. Several researchers including Hirsch, Schmandt and Stephens, Riew, Cohn, and Hanson have examined economies of size in public education. Hanson reported that, in general, school districts exhibited economies of size up to about 50,000 pupils in ADA (p. 92). Schmandt and Stephens thought schooling quality was closely related to expenditures. They reported that school district operations exhibited economies of size in providing a given quality of education but larger per capita expenditures were usually associated with larger populations.

In addition to differing levels of ADA per local school system, school systems also exhibit differences in the pupil-teacher ratio (PTR), average salaries paid to teachers ($AVSAL$) and average nonteacher instructional expenditures per classroom (INS). Increases in PTR tend to decrease expenditures, while increases in salaries and classroom expenses raise expenditures.

Exogenous influences also affect the demand equations of the system. Achievement is widely held to be greatly influenced by the socioeconomic background of the student (Coleman et al., Flanagan et al.). In this study, variables affecting achievement were

considered to be the county average mean years of schooling (*MYS*), percentage of the county's black population (*BLK*), and average student IQ scores in the county. A dummy variable (*LIQ*) was used to reflect differences in average IQ scores. The value of *LIQ* was 1 for those counties with average eighth grade IQ below 80 (approximately 4% of all counties) and 0 otherwise.

With respect to local effort, *LTE* was hypothesized to change with wealth as measured by the county property tax digest (*DIGEST*), to vary with dependency rates as measured by average daily attendance per capita (*ADA/POP*), to change as outside federal and state help per ADA (*OT*) increased or decreased, to change with the county's per capita income (*PCI*), and to vary among urban and rural counties as measured by population per county (*POP*).

Estimation Results

Secondary data from various agencies, particularly the Georgia Department of Education (1971, 1972), were used to estimate the simultaneous equations model.[2] Counties were used as the unit of analysis rather than school districts in order to better identify community characteristics. However, this simplification should not abstract from the school district decision-making process, as 83% of Georgia counties have county-wide school districts. Equations of the model were estimated by three-stage least squares; the coefficients and Student's t-values are shown below:

$$(5)\quad LTE = \underset{}{-0.316} + \underset{(1.99)}{0.026\,ACH} + \underset{(5.18)}{0.030\,DIGEST} + \underset{(4.49)}{0.108\,ADA/POP} + \underset{(5.76)}{0.622\,POP} - \underset{(-12.30)}{1.161\,PCI} - \underset{(-3.96)}{0.003\,OT},$$

$$(6)\quad ACH = 58.32 + \underset{(2.87)}{0.008\,EXP} + \underset{(8.04)}{1.418\,MYS} - \underset{(-19.69)}{0.207\,BLK} - \underset{(-5.51)}{6.548\,LIQ},$$

and

$$(7)\quad EXP = 549.2 + \underset{(2.59)}{1.272\,ACH} - \underset{(-3.94)}{3.028\,ADA} + \underset{(4.70)}{0.082\,(ADA)^2} - \underset{(-21.80)}{27.73\,PTR} + \underset{(12.08)}{51.81\,AVSAL} + \underset{(21.54)}{0.061\,INS}.$$

Implications inferred from the estimated signs of the equation coefficients are discussed below.

The reduced form equation for local tax effort is obtained by substituting the equation explaining achievement (*ACH*)—equation (6)—into the equation describing aggregate county demand (*LTE*)—equation (5). Since achievement is increasing with expenditure and aggregate demand (*LTE*) is increasing with achievement, the reduced form equation shows *LTE* to be a slightly upward sloping curve with regards to expenditures. Aggregate demand then shifts up or increases with increases in mean years of schooling in the population (*MYS*), decreases if the county has low average intelligence scores (*LIQ*), increases as wealth measured by property tax digest (*DIGEST*) increases, and shifts up with an increase in dependency rates (*ADA/POP*). The study showed significantly through equation (5) that local demand decreased as state and federal aid increased (*OT*). Thus, in some cases while it appears desirable to increase the level of outside help to bring supply-demand relationships into equilibrium, this can only be done at the sacrifice of local effort. The LTE ratio decreases as incomes increase.

Signs of the variables in equation (7) indicate that costs increase as average salaries increase, as average instructional expenditures per classroom increase, and as the average pupil-teacher ratio decreases. Expenditures also increase with achievement indicating that school administrators tend to spend more where results have been good. As *ADA* increases from the lowest levels, expenditures fall until the minimum cost of *EXP* with respect to *ADA* is reached. Thereafter, increases in *ADA* will cause expenditures to rise.

Power Equalization

This section applies the supply and demand relationships estimated above in order to

[2] Specific data sources include U.S. Department of Commerce for population characteristics, Georgia Department of Revenue for tax digest, and Georgia Department of Education (1971, 1972) for school expenditures and achievement scores.

quantify the impact of power equalization.[3] We will direct our attention to a form of power equalization that links state aid to the tax rate chosen by the community. This aid program would equalize the cost of any expenditure level for the local district. The level of spending for each district is determined by equilibrium supply-demand considerations.

Under power equalization, the level of state aid received by a locality will depend on the ratio of its wealth to that of some other key district as specified by the state. Selection of the key district is important in determining the appropriate level of state aid, as shown by the formula for determining the state's contribution to educational expenditures: state aid ratio $= 1 - \frac{\text{local wealth}}{\text{key district wealth}}$. For example, if a school district's wealth is 10% of the key district's wealth, the state will fund 90% of any total expenditure level selected by the district.

Using an average district as the key tends to redistribute wealth. When equalizing a low wealth district to an above average district, the state adds wealth to the average local wealth (Coons, Clune, and Sugarman). The particular power equalization program used in this analysis is one in which the aggregate level of state funding was held constant at its actual level. Although state aid for a specific district would be dependent on supply-demand considerations, federal aid was assumed to remain at its actual level for the district. Since the state accounted for 49.1% of total educational funding, the wealth level selected for the key district was above average in order to maintain aggregate state funding.[4]

Simulation Procedure

From equation (5), wealth as measured by tax digest per ADA was identified as an important demand shifter. Under power equalization, the effective level of wealth used in estimating each county's demand for educational services would be the same. Even so, demand for education would still be variable among counties as would their equilibrium expenditures on education.

Before introducing the power equalization option, it is important to examine the process by which equilibrium in the present model is reached. From equation (4), equilibrium is defined as the source of funds—local contributions and outside aid—being equal to the cost of education. Power equalization will shift the local tax effort or demand curve by changing the district's effective level of wealth. The new level of demand will intersect with costs to determine an equilibrium expenditure and hence the level of available state aid. For a given level of outside help, state aid, and county income, a county must adjust local effort until the cost of education is just equal to all available funds. This adjustment process would be necessary if factors affecting the cost of education, such as teacher salaries, nonteacher classroom expenditures, and pupil-teacher ratios, were inflexible. In this case, each district would be forced to raise local taxes until the cost of education would be covered. On the other hand, if these expenditures could be modified, equilibrium would be reached by increasing or decreasing these expenditures until local contributions and all outside aid were just equal to education expenditures. Both adjustment processes will be examined through an iterative procedure, programmed to adjust either the level of total expenditures or local effort and corresponding outside aid, while satisfying the estimated model.

Simulation Results

Actual expenditures (current operating expenditures minus transportation costs) averaged \$588 per ADA with a standard deviation of \$107. With an adjustment framework in which total expenditures would be adjusted so as to equate the sum of local contributions and state aid with total expenditures, average expenditures would be reduced 9%. Since this adjustment process would more effectively reflect differences in local demand for education, the variability in expenditures among districts would increase. The standard deviation of expenditures would be \$139. If expenditure components were taken as given and the school district had to increase local taxes to make up the difference between total cost and

[3] There may be some question as to the reliability of estimating school district response to power equalization that may collect more taxes from some districts than they spend on schools when based on data where all have some state aid. However, extrapolation from available data should certainly be considered as an important step in evaluating this policy alternative.

[4] County digests ranged from a low of \$22,000 per ADA to a high of \$92,000 per ADA. Assuming that schooling expenditures would be inflexible downward and that the state wished to maintain its present level of school funding, the digest selected as the key district would be \$65,000 per ADA.

outside aid, average expenditures would be 6% higher than actual expenditures, with a standard deviation of $110. In both cases, state aid is determined by the district's wealth and its local effort. Since it was assumed that aggregate outside aid would be held constant, differences in the average expenditure would also reflect differences in local contributions. Although these state averages are informative, it is also important to examine the impact of power equalization on districts with different characteristics.

Equilibrium tax efforts under the power equalization program were compared to actual tax efforts on a county by county basis. Results are summarized in table 1 by district wealth and in table 2 by population size. For both characteristics, counties were divided into three groups with an equal number of counties in each group. Local expenditures and state and federal expenditures reported in these tables reflect the portion of total expenditures that are financed by local sources and state and federal sources, respectively.

Since the state will share in the cost of improving the quality of education, poorer districts have an incentive to increase local effort under power equalization. The one-third poorest counties in terms of digest per ADA have the highest expenditure per ADA under power equalization relative to actual expenditures (table 1). However, the absolute level of expenditures is higher in the wealthier counties, which reflects greater demand for educational services in these counties. Power equalization results in some income redistribution. The one-third poorest counties would receive an increase in aid of $30 to $50 per ADA compared to a similar reduction in the one-third wealthiest counties.

The level of spending selected by individual counties would depend on the flexibility of

educational expenditures. If expenditures were flexible downward, average expenditures would be reduced in all three wealth categories (table 1). However, if these expenditures were rigid downward, equilibrium expenditures would be slightly above actual levels, reflecting that a few districts would choose higher expenditure levels while none would be able to lower their expenditures.

There is a direct relationship between total expenditures and county population (table 2). This relationship reflects the fact that rural residents have a lower effective demand for education. However, the cost of providing education is also lower in rural areas as reflected by equilibrium expenditures in the case of inflexible expenditures (table 2). Power equalization would result in a redistribution of aid that would favor urban counties. Even in the case in which outside aid was higher for rural counties, it was still lower than actual aid (table 2).

Further Implications

Major advantages of power equalization include local control of educational expenditures and uniform burden of financing additional educational services for taxpayers in similar situations. Decision making with respect to expenditure levels is kept on the local district level. Rather than forcing all districts to accept the same level of expenditures, each local district can select an expenditure level that would be appropriate for its needs and tastes. However, expenditure levels would not be based on the local school district's wealth. Since a given tax effort—taxes per dollar of wealth—would support the same level of educational services, disparities in educational expenditures would not be wealth induced. Thus, an individual's tax burden would be based on the quality of education that his community desired and not the community's wealth.

* Counties were divided into three groups with an equal number of counties in each group.

We have utilized two adjustment frameworks in analyzing the power equalization program. Deciding which framework is most appropriate hinges on the flexibility in educational expenditures. Such expenditures as teacher salaries and nonteacher classroom expenditures are more likely to be rigid downward in the short run. Only in the long run would district demand play a role in retarding increases in these expenditures so that expenditures would be brought in line with desired levels of educational services.

To this point we have said little about the limitations of power equalization. However, the approach does have some shortcomings: (*a*) the level of educational expenditures may vary excessively, (*b*) there may be a tendency for parents to switch their children to private schools, (*c*) it may be politically infeasible to take financial resources away from education in wealthier districts, and (*d*) public school finance will still be dependent primarily on the property tax.

Disparities in educational expenditures persist with power equalization; the data for Georgia revealed that power equalization would not reduce variability in educational expenditures. In the short run, power equalization would have little impact on variability of expenditures, but in the long run variability would increase, reflecting differences in local districts' demand for educational services. Disparities would also reflect differences in scale and factor prices rather than simply differences in ability to support education.

Power equalization takes resources away from education in wealthy districts. Thus, wealthy parents may choose to place their children in private schools rather than call for greater support of public education within the local district. This conclusion assumes that wealthy property owners are primarily responsible for determining the level of educational support. Since this may or may not be true, further research is required before this criticism can be properly evaluated.

Present equalization programs for education achieve only a modest redistribution of resources to poorer districts. Each local district's share of the minimum foundation program is inversely related to its wealth. However, most programs include a minimum guarantee that ensures that even wealthy districts will receive substantial state support. All districts are eligible for additional state funds through various provisions of the aid programs. As an example of the final distribution of state aid funds, actual state aid per student in Georgia ranged from \$197 to \$488, with some wealthy districts receiving above average levels. Provisions that effectively restrict the present program's ability to redistribute income were included to gain acceptance for the program from wealthy districts. Since a power equalization program has no such provisions, widespread political acceptance may be more difficult to achieve.

The property tax is continually under criticism: as an efficiency destroying excise tax placed on housing, as a burden on the elderly, and as the most regressive tax in the present public finance system. Despite all of these criticisms, we have not seen fit to substantially replace the property tax. Indeed, recent evidence questions many of these criticisms (Lindholm). Thus, the task remains to modify the property tax to overcome its major weaknesses. Power equalization is one such reform that would improve the property tax's use in financing public services.

Summary and Conclusions

Interdistrict inequity is one of the most pressing problems in school finance. Although landmark court decisions call for reform in school finance, states still have a great deal of flexibility in determining how equity problems will be solved. This paper has analyzed implications of one of the most popular reform proposals—power equalization. Implementation of power equalization in Georgia would result in a relative increase in expenditures in districts with lower levels of wealth, as well as a reduction in local effort for these districts. Rural counties, on the average, would lose state aid if the program was implemented.

Power equalization offers individual districts greater financial incentive and control. At the same time educational opportunities are dependent upon the local district's effort to support education and not on its wealth. Rather than using an arbitrary foundation level based on state-designated needs, each district can determine its own educational program based on such factors as special needs, tastes, scale considerations, and factor prices.

Optimizing Subindustry Marketing Organizations: A Network Analysis Approach

Stephen W. Fuller, Paul Randolph, and Darwin Klingman

A technique for solving large-scale mixed-integer plant-location problems is developed and utilized. The plant-location problem is formulated as a minimum-cost-flow network problem and solved with a special purpose network code in conjunction with implicit enumeration. Implicit enumeration reduces the number of plant combinations that need to be examined. The technique was applied to resolve a cotton-ginning subindustry's least-cost organizational adjustment to exogenous factors and involved consideration of short-run plant costs that were piecewise linear with fixed charges, two-levels of variable labor cost, storage costs, and assembly costs.

Key words: cotton gins, mixed-integer location problems, plant location.

The problem of estimating efficient market areas or marketing subindustry organization has received extensive treatment in the *Journal*. Early models developed and applied by French, Henry and Seagraves, Olson, and Williamson treated space as continuous and assumed that a region had uniform average density of supply or demand. The solution specified the most efficient plant size and corresponding market area dimensions. A later model development by Stollsteimer was capable of including preselected potential plant locations and discrete supply or demand locations. The solution communicated least-cost number, size, and location of marketing facilities. Recent extensions of the basic Stollsteimer model by Polopolus, Chern and Polopolus, Ladd and Halvorson, and Warrack and Fletcher have enabled the applied researcher to incorporate additional realism, test sensitivity of solution, and increase size of plant-location problems. King and Logan applied a transshipment model to a plant-location problem where materials may move from a supply point through another intermediate supply point and on to the demand point and/or through an intermediate demand point. Hurt and Tramel and Leath and Martin have extended this model to incorporate additional realism. Toft, Cassidy, and McCarthy have developed a sensitivity test to determine the stability of solutions obtained with the transshipment model. To accommodate those situations in which nonlinear long-run total processing costs exist, Kloth and Blakely employed separable programming, while Candler, Snyder, and Faught used concave programming.

This article reports on a plant-location model developed to determine a processing industry's least-cost organizational adjustment to a region's decreased raw product output and new storage technology. Existing plant-location solution procedures were unable to incorporate necessary realism and, if modified to do so, generally required extensive computer time to obtain a solution. To overcome these limitations, a locational problem was formulated as a network problem and solved with the use of a special purpose primal simplex code in combination with implicit enumeration. This solution procedure should be of general interest to applied economists involved in locational analysis.

The location problem focuses on the trade-offs between plant numbers or cost and transportation cost, storage cost, and payment of

overtime plant-labor costs. The objective was to specify which processing facilities to activate and the spatial and temporal flow of raw product to the activated plants in order to minimize the total cost of assembly, storage, and processing.

Problem Situation

Cotton production in several southwestern irrigated valleys has decreased by 50% during the past decade, while regional processing (ginning) capacity has remained relatively unchanged. Furthermore, recent innovations in seed cotton storage permit extension of assembly and processing activities beyond the current harvest period, thus decreasing an area's required processing capacity.[1] Because of the nature of variable plant costs and the feasibility of seed cotton storage, it was hypothesized that total system costs could be decreased from current levels by reducing the number of operating plants.

Each plant in this study has a unique, piecewise linear variable cost function with a positive intercept (figure 1). The positive intercept value represents a one-time annual fixed charge for activating and operating a plant and includes costs of salaried management personnel and an electrical fee. The electrical fee purchases sufficient electrical power to process that volume associated with the juncture of the linear segments constituting the plant-cost function (V_j). Consequently, marginal cost up to V_j is less than that beyond V_j.

Plants have the opportunity to increase weekly and seasonal output by employing multiple labor shifts. Thus, there are two levels of variable labor cost associated with each plant—one for the regular shifts and another for overtime labor shifts. If the capacity of the regular shift is exceeded, all of the additional cotton must be processed at the more expensive overtime rate. However, prudent use of overtime may be cost saving if it avoids the necessity of activating an additional plant.

Additional cost trade-offs exist between the region's number of operating plants and total assembly costs; that is, as plants are activated, the average assembly distance decreases,

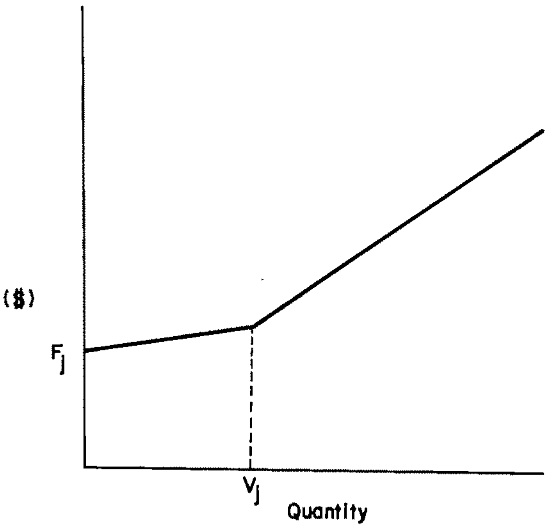

Figure 1. Total variable plant cost exclusive of variable labor cost

which affects reductions in assembly cost. In addition, reducing regional processing capacity below the peak-week harvest output necessitates the storage of seed cotton, thus adding an additional cost to the system. However, seed cotton storage may be preferable to activating an additional plant.

An optimal solution to the problem is one that minimizes aggregated costs of assembly, storage, and processing for the region's ginning industry. In particular, the solution must designate which plants to activate for the season, quantity of seed cotton to be field-stored, quantity of seed cotton to be assembled per week from specific production locations to activated plants, and the amount of cotton processed at each activated plant per week.

Mathematical Representation of the Problem

Let m represent the number of production locations, n the number of existing plants, and W the number of weeks in the planning period. The weekly quantities of raw product at each production location are known and are denoted by $P_{1k}, \ldots, P_{mk}$, where $k = 1, \ldots, W$. Also, the weekly capacities of each of the existing plants are known and are denoted as $K'_1, \ldots, K'_n$ for output processed during regular hours and $K''_1, \ldots, K''_n$ for output processed during overtime hours. Furthermore, let the costs at the jth plant be denoted by r'_j = marginal labor cost incurred

[1] Storage is accomplished with a rick compactor that forms a stack of seed cotton approximately 8 feet wide and 6 feet high at a density of 7 pounds per cubic foot. Once the peak harvesting period has passed, the stored seed cotton is loaded into trailers and shipped to operating plants for processing.

during regular hours, r''_j = marginal labor cost incurred during overtime hours, where $r'_j < r''_j$, F_j = annual fixed charge associated with activating plant j, c'_j = marginal cost exclusive of labor associated with plant j's initial linear cost segment, and c''_j = marginal cost exclusive of labor associated with plant j's second linear cost segment, where the juncture point between the two segments is at V_j for plant j and $c'_j < c''_j$.

The cost of placing the raw product into storage and then later removing it represents a one-time cost that is independent of the production origin, the activated plants, and the time period. Let S represent the unit storage cost. Furthermore, the assembly cost between each pair of production locations and existing plant sites is proportional to the quantity shipped and the distance between the production location and the plant site. Let t_{ij} represent the unit assembly cost from production location i to plant j's location site. The problem is to select a configuration R of the n existing plants such that the aggregated cost of assembly, storage, and processing is minimized and all raw material is processed without exceeding plant capacities.

To obtain a mathematical model of this problem, the following decision variables are defined: y_j = a binary variable where $y_j = 1$ when plant j is activated and $y_j = 0$ when plant j remains closed, X'_{ijk} = quantity of raw product available at production location i and processed at plant j in week k during regular hours, X''_{ijk} = quantity of raw product available at production location i and processed at plant j in week k during overtime hours, S'_{ijkl} = quantity of raw product stored at production location i in week k and then processed at plant j during regular hours in week l, and S''_{ijkl} = quantity of raw product stored at production location i in week k and then processed at plant j during overtime hours in week l. From these decision variables, it is possible to determine the total amount of raw product processed at plant j, (X_j). It is then possible to separate X_j as follows:

$$X'_j = \begin{cases} X_j \text{ if } X_j \le V_j \\ V_j \text{ if } X_j > V_j \end{cases}$$

and

$$X''_j = \begin{cases} 0 \text{ if } X_j \le V_j \\ X_j - V_j \text{ if } X_j > V_j \end{cases}.$$

Then the mathematical model of the problem is as follows. Determine the values of the decision variables such that total systems cost (Z) is minimized, where

$$\begin{aligned} Z = \sum_{j=1}^{n} y_j \Bigg[& F_j + c'_j X'_j + c_j V_j + c''_j X''_j \\ & + r'_j \left(\sum_{i=1}^{m} \left(\sum_{k=1}^{W} X'_{ijk} + \sum_{l=1}^{W} \sum_{k=1}^{l} S'_{ijkl} \right) \right) \\ & + r''_j \left(\sum_{i=1}^{m} \left(\sum_{k=1}^{W} X''_{ijk} + \sum_{l=1}^{W} \sum_{k=1}^{l} S''_{ijkl} \right) \right) \\ & + S \sum_{i=1}^{m} \sum_{l=1}^{W} \sum_{k=1}^{l} (S'_{ijkl} + S''_{ijkl}) \\ & + \sum_{i=1}^{m} \left(t_{ij} \left(\sum_{k=1}^{W} (X'_{ijk} + X''_{ijk}) \right. \right. \\ & \left. \left. + \sum_{l=1}^{W} \sum_{k=1}^{l} (S'_{ijkl} + S''_{ijkl}) \right) \right) \Bigg] \end{aligned}$$

is subject to the following conditions.

All raw product available at production location i in week k is either processed or stored,

$$\sum_{j=1}^{n} y_j \, (X'_{ijk} + X''_{ijk} + S'_{ijkl} + S''_{ijkl}) = P_{ik},$$

for $i = 1, \ldots, n$; $k = 1, \ldots, W$; and $l = k + 1, \ldots, W$. The plant's weekly processing capacity associated with regular processing hours must not be exceeded. For plant j in week l, this is

$$\sum_{i=1}^{m} (X'_{ijl} + \sum_{k=1}^{l-1} S'_{ijkl}) \le K'_j,$$

for $j = 1, \ldots, n$, and $l = 1, \ldots, W$. The plant's weekly processing capacity associated with overtime processing hours must not be exceeded. For plant j in week l, this is

$$\sum_{i=1}^{m} (X''_{ijl} + \sum_{k=1}^{l-1} S''_{ijkl}) \le K''_j,$$

for $j = 1, \ldots, n$, and $l = 1, \ldots, W$. Restrictions on the decision variables are $X'_{ijk} \ge 0$; $X''_{ijk} \ge 0$; $S'_{ijkl} \ge 0$; $S''_{ijkl} \ge 0$, and $y_j = 0$ or 1. To determine total seasonal output for plant j $(X'_j + X''_j)$, the following accounting equation is specified:

$$\sum_{i=1}^{m} \left(\sum_{i=1}^{m} (X'_{ijk} + X''_{ijk}) + \sum_{l=1}^{W} \sum_{k=1}^{l} (S'_{ijkl} + S''_{ijkl}) \right) = X_j,$$

for $j = 1, \ldots, n$.

The above mathematical model is a mixed integer 0-1 linear programming problem. Conceptually, the problem could be solved using a standard mixed-integer linear programming computer code. However, for the problem under consideration (139 production locations, 14 processing plants, and 16 production weeks), the problem dimensions exceed the solution capability of any known mixed-integer computer code. To the author's knowledge, the mixed-integer programming systems available from leading computer manufacturers are the most capable of any existing computer codes for solving large mixed-integer programming problems. Examples of these codes include the APEX III programming system available from the Control Data Corporation and the mixed-integer code available with International Business Machines Corporation's MPSX system. It is estimated that 800 computer hours would be required to solve the problem under consideration, given these mixed-integer computer codes capabilities.

Recent developments and computational testing have shown that special purpose computer codes for solving minimum-cost-flow network problems are 100 to 150 times faster than the best general purpose commercial linear programming computer codes; thus, the problem was reformulated as a network problem (Glover, Karney, and Klingman 1973). The following section presents a network formulation of the problem that is mathematically equivalent to the above formulation; that is, to formulate the problem as a network problem, no simplifying assumptions are made. Thus, solving either formulation of the problem will yield the same optimum.

Network Formulation

A network consists of a number of nodes or junction points, each joined to some or all of the others by arcs. Nodes are diagrammed as circles, while arcs are indicated by lines or line segments. The crossing of arcs does not indicate intersection of corresponding arcs except at nodes. The unidirectional flow of raw product is represented by an arrow placed on an arc. To exhibit the structure of the cost-flow network, a prototype of the above problem is formulated in figures 2 and 3. A portion of the network shown in figure 2 is enlarged and shown in figure 3.

The prototype problem involves two production locations that produce raw product for two consecutive weeks and two existing plants that may operate these two weeks plus one additional week. Level iAk nodes represent production location i in week k, while P_{ik} depicts the raw product produced at location i in week k. In the example, a total of four production nodes are represented. In addition, associated with each production location node are arcs that connect it with the jBl nodes, where the node jBl represents available processing at plant j during week l. On the arcs connecting the iAk level nodes with the jBl level nodes, there is the unit assembly (t_{ij}) and a one-time unit storage cost (S) if the value of l associated with the jBl level node is greater than the value of k associated with the iAk level node. All of the raw product processed in each plant during the three weeks is then channeled through a single node called the weekly master node for that plant. The jC level node corresponds to the weekly master node for plant j. Two arcs connect each jBl level node with the jC level node. One arc represents processing at plant j without use of overtime labor. Such arcs have a weekly capacity of K'_j and a unit cost of r'_j. The second arc represents weekly overtime processing capacity of K''_j and associated unit cost of r''_j.

To accommodate the two levels of marginal cost associated with the two linear segments comprising each plant's cost function, D level nodes are introduced. Two arcs connect each C and D level node. One arc is for the marginal cost c'_j and has a capacity given by volume V_j. This arc represents the jth plant's first linear-cost segment, while the second arc is for marginal cost c''_j and represents the second linear-cost segment.

Finally, all flow is channeled through a single node, node E, which acts as a sink for the entire raw product production. The arc from node jD to node E has an upper bound or capacity restraint of Uy_j on its flow, where U equals the sum of production of all production locations for the season and has a unit cost of 0 (figure 3). This capacity restraint has the following effect. If $y_j = 0$, then plant j cannot process any raw product during the entire season. Therefore, it is not activated. Otherwise, $y_j = 1$, and plant j can process any amount of raw product subject to the other restraints within the model.

Each arc in figure 3 has the marginal cost

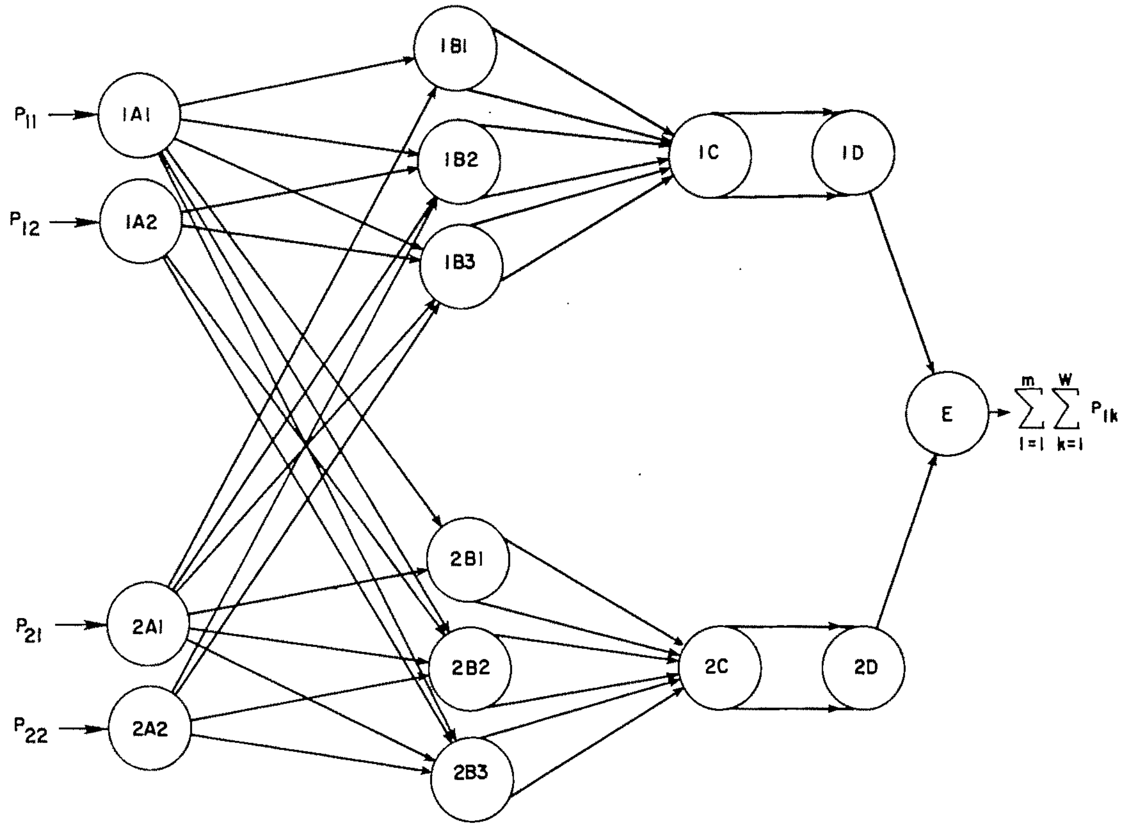

Figure 2. Network diagram of prototype problem

and the appropriate upper and lower bounds associated with each arc for that portion of the network associated with production location 1. Absence of a lower bound indicates a lower bound of 0. Plant capacities K'_j, K''_j, and V_j represent upper flow bounds. The network problem can be stated as follows: for a given set of plants, find the least-cost flow of goods through the network such that the flow does not violate the flow bounds on each arc.

Network Solution Procedure

The above network model can be solved as follows. Arbitrarily fix the value of the y_j variables to 0 or 1, then solve the remaining problem (the subproblem) to find a set of flows on the arcs that satisfy the capacity restrictions on the arcs and the input and output restrictions on the nodes at minimum cost. Once the values of the y_j variables have been selected, the subproblem to be solved is called a minimum-cost-flow network problem. A recently developed, highly efficient minimum-cost-flow network computer code by Glover, Klingman, and Karney was used to solve the subproblems (1974).

Conceptually, the solution procedure involves implicitly setting the y_j variables to every possible combination of values (0's or 1's) and solving the associated subproblem for each combination. After each subproblem has been solved, the total of the fixed charges for those plants scheduled for processing is then added to the total cost of the subproblem. The optimal solution is that one that is the minimum of all combinations.

The efficiency of this solution approach depends on the solution speed of the network code and the number of subproblems that actually have to be solved. The total number of subproblems is $2^n - 1$. Unfortunately, this number is often large, e.g., for $n = 14$, there is a total of 16,383 subproblems. In order to avoid explicitly solving all subproblems, a highly effective implicit enumeration procedure was employed. The following section gives an overview of this procedure.

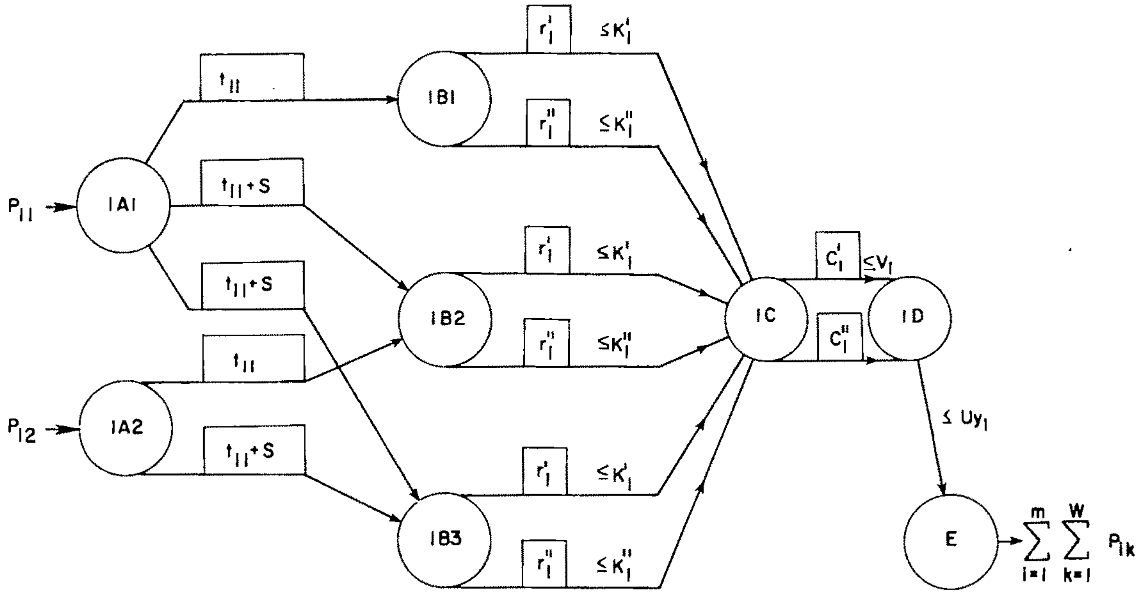

Figure 3. Enlarged network diagram of prototype problem for production location 1

Implicit Enumeration Procedure

Implicit enumeration is an organized method of complete enumeration in which only those combinations that can improve a previously enumerated combination are examined. To apply implicit enumeration, the problem is pictured as searching a logic tree composed of branches and nodes. The search proceeds along a branch until it becomes obvious that continued progress along a given branch is unnecessary because the best possible payoff on that branch can be shown to be inferior to payoffs already observed on other branches. In this way, only partial examination of most branches needs to be considered, thus significantly reducing the number of combinations considered.

To illustrate the concept of implicit enumeration, consider a prototype problem involving four plants (figure 4). The associated logic tree illustrates all combinations of plants that may be deactivated. Each node in the tree represents a combination of plants that are deactivated. Those plants not designated in a node are considered activated.

Fixed charges associated with activated plant combinations are aggregated with that combination's optimal assembly, storing, and processing costs determined via the network code. Node [0] in the logic tree corresponds to the least-cost solution found when all plants are activated and total costs are represented by TC_0. Node [1] represents the objective function value when the problem is optimized with plant 1 deactivated. Let TC_1 represent the resulting total cost. There are three possible outcomes (*a*) $TC_0 < TC_1$, in which case the removal of plant 1 has increased the costs being minimized. Thus, this branch may be removed from the tree, since the solution will always be improved by utilizing plant 1. Similarly, all nodes in other branches of the tree that do not have plant 1 operating may be removed. (*b*) $TC_0 > TC_1$, in which case the objective function value has decreased by deactivating plant 1. In this case, no nodes of the tree may be removed. Thus, one continues to move through this branch of the logic tree. (*c*) The solution is infeasible with plant 1 deactivated. In this case, as in case 1, this branch of the tree and all nodes in other branches that do not utilize plant 1 may be removed.

When all branches have been explicitly or implicitly traced, the last nodes of each branch are compared to each other. The node with the smallest objective function value represents the optimal plant combination.

The specific techniques for implicit enumeration vary widely among problems, and the above general description represents a simplification of the technique actually used in this problem. For details of the employed branching rules, see Klingman, Randolph, and Fuller. Table 1 contains solution time statistics on several problems to illustrate the ef-

ficiency of both the network code and the implicit enumeration procedure.[2] The solution times indicate that it is quite feasible to solve large problems of this type.

Application Results

The ginning industry under study is located in an irrigated portion of the Rio Grande Valley that traverses Texas and New Mexico. The study area is approximately 90 miles in length and varies from 1/4 to 7 miles in width. Fourteen single plant firms currently operate in this area and process the area's 43,000 bales of annual production. In the early 1960s, the study area produced approximately 85,000 bales, which were processed at sixteen area plants. Because of the relative stability of the area's processing capacity, excess plant capacity has developed. Furthermore, recent innovations in seed cotton storage would permit reductions in gin plant numbers by removing the interdependence of harvesting and ginning activities. The above model was applied to this situation to resolve least-cost industry organization.

A substantial resource commitment was necessary to develop data inputs for this model application. A 139 × 14 matrix relating production, production locations, and distance to existing gin sites was developed from aerial photos and Agricultural Stabilization and Conservation Service data. Work measurement data was collected on the fourteen plants by the work sampling technique. Input-output parameters for energy, plant downtime and physical capacity utilization characteristics, and other technical aspects of production affecting variable cost were obtained by monitoring plants throughout the 1973–74 season (Fuller and Washburn). The assembly activity's production characteristics were recorded on the area system, while the storage system input-output parameters were determined by monitoring an area that had previously adopted this technology. Once production functions had been specified, the cost functions were determined by applying factor prices. The plant's cost and physical capacity characteristics are shown in table 2. Storage and assembly costs were estimated to be \$6.01 per stored bale and \$0.42 per bale-mile, respectively.

Because of the ginning industry's excess processing capacity, all plants will not need to operate to accommodate the peak-harvest output level. Therefore, some reduction in plant numbers and associated plant cost would be available without introduction of seed cotton storage. To separate those plant cost savings attributable to removal of excess processing capacity from those due to the seed cotton storage technology, three alternative solutions were resolved. The first solution was a simulation of the existing system costs (assembly and processing) and involved the fourteen gin plants operating at their 1974 output levels. The second solution was the optimal organization attainable with the opportunity for storage. The third solution reflected the optimal industry organization attainable without the opportunity for storage. This was accomplished by removing storage arcs between the A and B level nodes. By contrasting the three solutions, cost savings available with the removal of excess plant capacity and introduction of seed cotton storage technology were isolated (table 3).

Optimum Industry Organization with Storage

The optimum industry organization involved the operation of six plants (plants A, E, G, H, J, and M) rather than the existing fourteen. To increase the activated plants' annual volume, approximately 7% of the region's cotton production was processed during overtime shifts, whereas slightly over 10% of the production was stored. Utilization of overtime shifts and storage occurred during peak-harvest weeks when harvested output exceeded processing capacity. Immediately following peak-week harvest output, cotton was removed from storage and processed during the plants' regu-

[2] The computer system is proprietary. Information on the availability of the code may be obtained by contacting Professor Darwin Klingman, BEB-608, University of Texas, Austin, Texas 78712.

lar labor shifts. In addition, each activated plant remained open throughout the sixteen-week harvest season; i.e., plants were not opened and closed weekly as the solution procedure permitted.

The six activated plants were on the average of slightly greater capacity and lower unit variable cost than the closed facilities. As shown in table 2, the activated plants were generally the most labor efficient. Even though the plant's annual fixed charges must have strongly influenced optimal plant numbers, they varied little between plants and accordingly had an insignificant effect on plant selection. Storage cost was favorably affected by selecting larger than average plant sizes, since this reduced the quantity of seed cotton that required storage. Storage was system-cost reducing; however, additional storage could have been utilized. With additional storage, several more plants could have been deactivated, as twenty-two weeks were available for processing. Clearly, cost savings (fixed charges) associated with further reductions in plant numbers failed to offset increases in storage, assembly, and overtime labor costs. In addition, the optimal solution revealed several effects of assembly costs. First, the locational configuration of selected plants closely approximated one predicted by a priori rea-

Table 3. Contrasted Characteristics of Actual and Optimum Short-Run Industry Organizations

Organization	Number of Operated Plants	Plant Cost[a]	Storage Cost[b]	Assembly Cost[b]	Total System Cost
		$			
Actual	14	528,122	0	69,167	597,289
Optimum without storage	9	445,065	0	71,326	516,391
Optimum with storage	6	393,018	26,786	80,970	500,775

[a] Includes those variable costs that tend to vary between plants—seasonal office and gin plant labor, utilities, repairs, and drying fuel. Does not include plant fixed costs, bagging and ties, office supplies, office utilities, advertising, travel, and miscellaneous costs.
[b] Includes fixed and variable costs.

soning; i.e., plants were evenly dispersed throughout the production region with modification for locational pull associated with more intensive production areas. Second, in those weeks when processing capacity exceeded processing demand, cotton could have been routed to the more efficient of the six selected plants, i.e., the least efficient plants could have been closed. Since this did not occur, this implies that processing cost savings failed to offset assembly costs associated with the additional assembly distances.

Optimum Industry Organization without Storage

The optimum solution reflects industry organization with excess plant capacity removed. Characteristics of this solution are similar to that solution involving storage. The optimal organization involved the operation of nine plants, six of which were identical to those activated in the storage solution. Activated plants were A, C, E, G, H, I, J, M, and N. Approximately 4% of the region's cotton production was processed during overtime shifts that were used in those weeks when harvested output exceeded processing capacity. Again, the solution revealed no cost advantage to opening and closing plants on a weekly basis.

The optimal organization revealed that system costs were minimized by reducing plant numbers to the maximum feasible extent. Reducing area plant numbers so that industry processing capacity is just capable of meeting peak-week harvested output through use of overtime labor shifts was cost advantageous. Gin plant cost savings, associated with reducing plant numbers, more than offset increases in assembly and overtime labor costs.

Implementation and Implication of Solutions

The analysis indicates that most of the potential savings can be realized by reorganizing the study area ginning industry to reflect removal of its excess capacity; that is, seed cotton storage technology need not be introduced. Adopting the reorganization scheme that involves no storage would reduce system costs $1.88 per bale, a saving of 14%. This alternative could be implemented without investment in new capital. The reorganization alternative that involves storage would yield a saving of $0.36 per bale relative to the organization involving no storage. Based on existing cotton production levels and on savings attributable to storage, approximately seven years would be required to capture capital expenditure associated with implementation of this alternative. Because of the study area's declining cotton production, decision makers are not inclined to invest new capital into the area's cotton-marketing system. Consequently, the reorganization scheme requiring no storage would appear most acceptable.

Currently, the study area ginning industry is comprised of fourteen single gin plant firms—eleven of these firms are producer cooperatives, while the remaining firms are partnerships. Because of the fragmented ownership structure of the study area industry, implementation of either scheme would require some firms to exit the industry or merge with remaining firms. For example, to implement the no-storage solution, three cooperatives and two partnerships would need to cease gin plant operation. It is difficult to predict whether either reorganization alternative will be implemented. During the past several years, personnel from the Extension Service have counseled with study area gin firms in an effort to thwart their deteriorating financial condition. Merger has been the principal alternative forwarded by extension personnel. Merger is a vehicle whereby much of the potential savings could be realized, since this would permit closing of the least efficient plants and/or reduction in gin plant management personnel, the principal source of savings. The results of this study have not been presented to the area decision makers; however, past efforts to bring firms together for merger negotiation have been unsuccessful. One of the undesirable effects of taking no action rests with the unfavorable efficiency characteristics of the financially strong firms. The newer, more efficient gin plants are owned by firms with the heaviest debt load and appear to be the first to exit the area industry. These plants may never reopen, since the remaining firms may prefer to operate the plants located within their immediate communities.

Optimizing subindustry spatial organization leads to the allocation of exclusive market areas, in which case there is an unavoidable conflict between competition and efficiency that stems from the element of spatial

monopoly. Therefore, operational efficiency gains may be offset by losses in pricing efficiency. Introducing either reorganization alternative into the study area may result in pricing efficiency losses; however, several circumstances reduce this threat. Ginning charges are monitored by a state agency that annually holds hearings for testimony on the fairness of charges proposed by area ginning industries. Consequently, excessive charges should not occur. In addition, the evolved ginning industry would probably include farmer-owned cooperatives, given the existing dominance of this form of business, in which case the threat of monopolistic power directed toward producers is diminished.

Summary

As applied economists endeavor to include additional realism into their locational analysis, conventional solution techniques become limiting and unaccommodating. The plant-location problem involved consideration of several dimensions not conveniently incorporated into existing location models. The problem involved consideration of (*a*) short-run costs unique to each plant but whose general form was piecewise linear with an annual fixed charge, (*b*) two levels of variable labor cost associated with regular and overtime work shifts and each shift's weekly output constraint, (*c*) storage cost, and (*d*) assembly cost between each pair of production locations and plant sites. The least-cost solution identified plants to be activated at alternative sites and quantity processed per week, weekly quantity processed at each plant in regular and overtime shifts, and the quantity to be stored per week.

To attain the desired realism in the model and to find a workable algorithm, the problem was formulated as a network problem and solved with a network computer code. This network abstraction not only provided greater insight into the structure of the problem but also opened the way to a feasible computer solution. Such an abstraction if applied to other locational problems should prove to be equally effective. Because a network model can easily accommodate a multiphase problem, it is less necessary to make certain simplifying and unrealistic assumptions. Furthermore, the computational efficiency gained by employing the network algorithm with implicit enumeration permits the investigation of larger locational problems than traditional solution approaches.

A Spatial Equilibrium Model for Plant Location and Interregional Trade

Matthias von Oppen and John T. Scott

Combination of a single-equation location model and interregional trade analysis into one model provides an effective tool to simultaneously determine regionally optimal numbers and sizes of processing plants and optimal interregional trading and pricing. The results of an earlier empirical application of the model on the prospective soybean industry in India are reviewed after four years of actual development. Private industry is allocating its processing plants in line with the pattern computed by the model, and a comparatively costly plan of arbitrarily establishing one government plant at an arbitrary location has not been implemented.

Key words: agricultural industry, India, interregional trade, location theory, soybeans.

The general theory pertaining to the spatial location of economic activity can be divided, according to Hoover, into the following three classes: location, regional analysis, and interregional trade. Location theory describes the economic analysis involved in comparing alternative spatial locations for a specified kind of activity, while regional analysis is "concerned with groupings of inter-related economic activities in proximity within certain specified areas" (Hoover, p. 3). Interregional trade refers to the buying and selling of inputs or products and their movement among two or more delineated areas.

Highly sophisticated methods and approaches have been separately developed in each of these fields of spatial economic theory. However, apparently few attempts have been made to integrate these theoretic fields, especially the theory of location and interregional trade analysis, or to integrate their associated models (Candler, Snyder, and Faught; Leuthold and Bawden; Rao; Stammer).

There are an increasing number of cases in which public decision makers, especially in developing countries, are concerned with the question of implementing a new, efficient agricultural industry (from raw materials production to processing and marketing of final products) so that social welfare can be maximized. To solve such a problem requires investigations in two fields: (*a*) an analysis of the interregional trade in order to predict the flows of the new goods, the quantities demanded regionally, and the resulting price level; and (*b*) a determination of optimal locations and sizes of individual processing plants. Therefore, we believe that an approach integrating the theory of location and interregional trade analysis will be of general interest. The model presented here was developed to represent the emerging soybean industry in India (von Oppen 1972), but it could be adopted to almost any agricultural production and processing industry.

The Model

The spatial equilibrium model for location of processing plants integrates all of the following important economic functions: (*a*) transportation of inputs and products, (*b*) average processing cost related to plant size, (*c*) size of market area per plant, (*d*) regional supply functions of inputs to be processed, and (*e*) regional consumer demand functions for processed products. The model is constructed in two parts: the plant location is determined with the help of a single equation optimization model and the interregional trade of inputs and products is analyzed by means of a quadratic

Takayama, University of Illinois, as well as J. G. Ryan and H. P. Binswanger, International Crops Research Institute for the Semi-Arid Tropics, for their helpful suggestions.

programming model. From the optimum solution of the plant location, model regional average processing costs are derived and fed into the interregional trade model. From the optimum solutions of interregional trade model, the quantities to be processed and distributed by processing plants are derived and fed into the plant location model. If applied in this fashion, both models are linked by an iterative solution procedure and jointly form a spatial equilibrium model for plant location and interregional trade (figure 1).

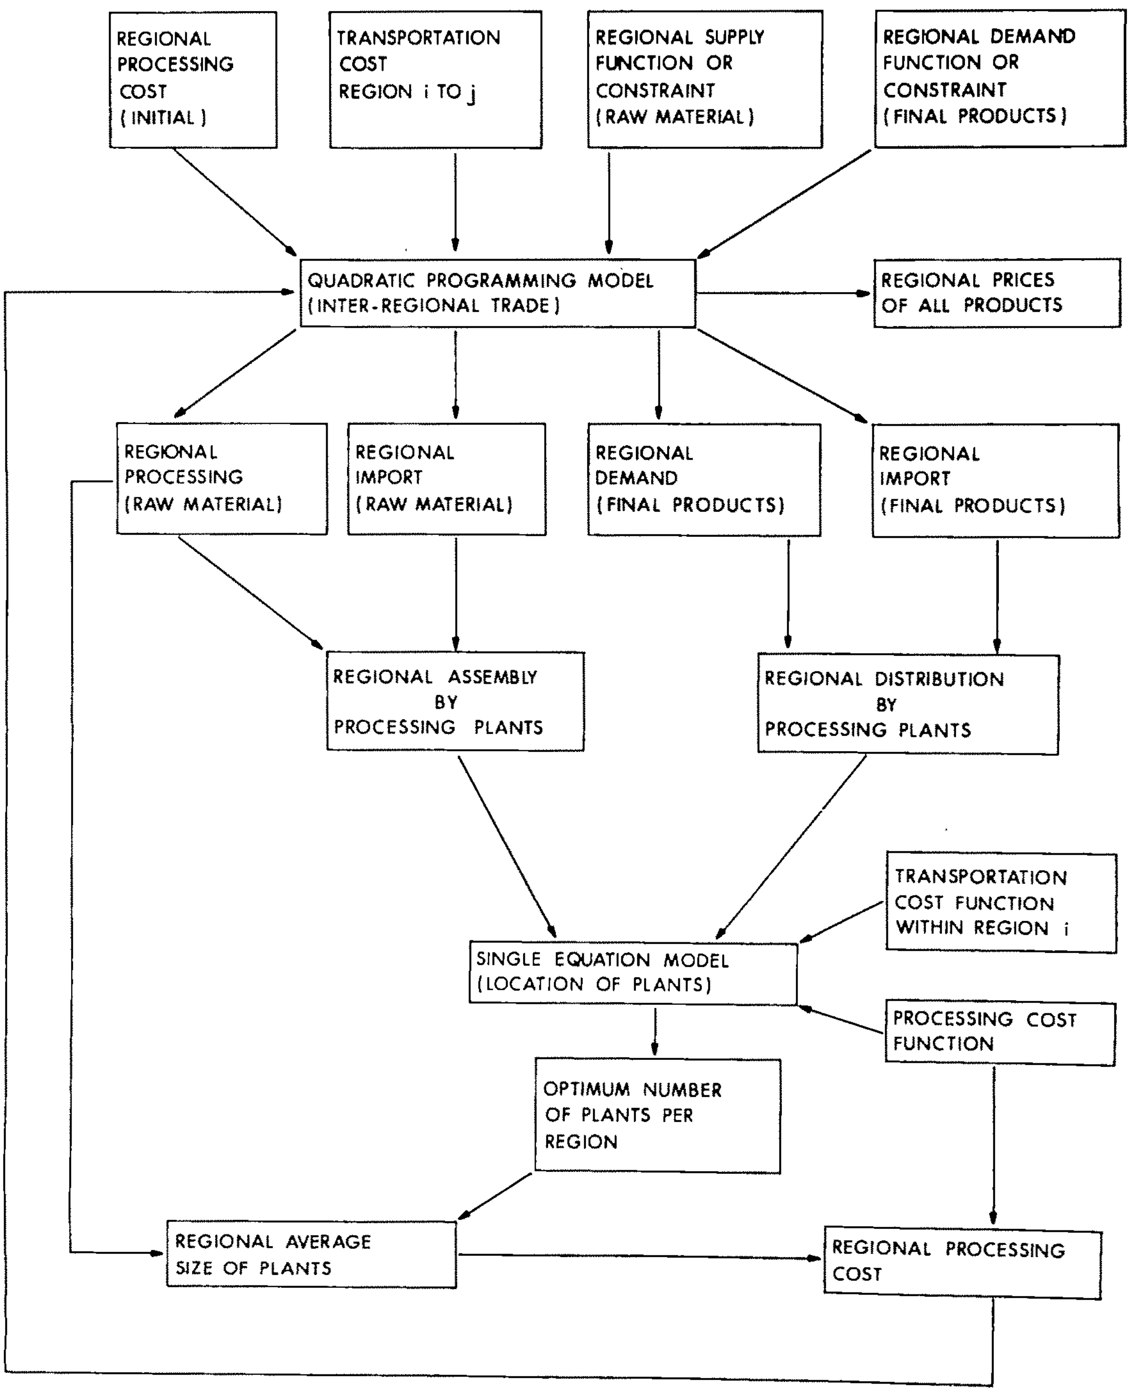

Figure 1. Flow chart of a spatial equilibrium model for plant location and interregional trade

Plant Location—Assembly, Processing, and Distribution

The location equation is based on the following assumptions: (*a*) as the number of plants within a region increases, average processing costs will increase at a linear rate; (*b*) both the average assembly and distribution costs of the major inputs and products in the market area of a plant decrease at a decreasing rate as the number of plants in a region increases; (*c*) the assembly and distribution road network fits approximately a 60° triangular grid such that hexogonally-shaped plant market areas within regions are appropriate; and (*d*) within a region, producers of inputs for the plant and consumers of products from the plant are evenly distributed.[1]

Furthermore, as the number of plants is initially increased (from the number at which plant size is large enough that average processing cost is a minimum), the sum of average assembly and distribution costs decreases faster than the increases in average processing cost. As the number of plants continues to increase, however, processing costs begin to increase faster than the decrease in assembly and distribution costs. The optimum number of evenly distributed plants is determined by the minimum of the sum of these average cost functions.

Given these assumptions, the plant location equation can be derived as follows:

$$B = 6\frac{r^2}{4}3^{1/2}, \tag{1}$$

where B = the hexagonal market area for a plant and r = the circumscribing radius of the hexagon. If A is the total area of the region for which the optimum number of plants is to be found and N is the number of plants, the area per plant can be explained as

$$B = \frac{A}{N}. \tag{2}$$

Solving equation (1) for r and substituting equation (2) into (1) gives

$$r = 0.6204\left(\frac{A}{N}\right)^{1/2} \tag{3}$$

for the radius of each of the N hexagons representing the market areas of the plants in the region. The average distance from all points evenly distributed within the hexagon to the central point for assembly and distribution can be shown to be $0.7r$.

We assume that assembly of raw material and distribution of final products have the same per unit costs and these are a linear function of the average distance from the plant with an initial fixed cost for loading or unloading and vehicle use, so that

$$T = f + d\,(0.7r), \tag{4}$$

where T = the transportation cost per unit of input or product, f = the fixed cost, and d = the per unit cost of transportation per unit distance.[2]

The quantities of raw materials (R) to be assembled for processing and the quantities of final products (M) to be distributed for consumption within the market area of the plant can be expressed in relative terms using as a common denominator the quantity regionally available for processing (Q).[3] Relative weights of the quantities transported within the market area of a plant are required to form the sum of the transportation cost functions for both of these quantities before adding the processing cost function. Thus, after substituting equation (3) into equation (4) and multiplying by the relative weights, the regional assembly cost function for locally assembled input R becomes

$$T_1 = T\frac{R}{Q} = f_1\frac{R}{Q} + (0.43)\,d\left(\frac{R}{Q}\right)A^{1/2}N^{-1/2}, \tag{5}$$

and the regional distribution cost function for locally distributed final product M becomes

$$T_2 = T\frac{M}{Q} = f_2\frac{M}{Q} + (0.43)\,d\left(\frac{M}{Q}\right)A^{1/2}N^{-1/2}. \tag{6}$$

The average regional processing cost is assumed to be

$$T_3 = f_3 + c\,\frac{N}{Q}, \tag{7}$$

[1] This assumption is perfectly fulfilled only in the case of perfectly homogeneous (i.e., for all practical purposes, very small) regions. However, even in the case of larger regions with urban population concentrations, the assumption may still be acceptable and realistic as long as these urban areas as such are evenly distributed.

[2] Where assembly and distribution are carried out by truck and as long as the commodities concerned are not extremely bulky, perishable, or otherwise difficult to be transported by truck, their freight rates normally are based on the same per quintal charge.

[3] Note that Q includes regional production adjusted by imports and exports of the region as determined from the interregional trade portion of the model (see figure 1).

where N/Q = the reciprocal of average plant capacity, and the processing cost is assumed to be a function of the reciprocal of the quantity processed.[4] Then summing the three functions (5), (6), and (7) and setting the first derivative of this sum with respect to N equal to 0 gives the number of plants (N^*) that according to the second order condition minimizes assembly, processing, and distribution costs:

$$(8)\quad N^* = \left(\frac{0.43}{2}\ \frac{d}{c}\ (R + M)\right)^{2/3} A^{1/3}.$$

This shows that the optimum number of plants is a linear homogeneous function of degree one in the two variables—the sum of inputs assembled and products distributed and the area of the region. This optimum number is then theoretically located by evenly distributing the plants within the region.

Interregional Trade—Regional Supply and Demand Functions

The basic concept of this model is a special case of the general problem of nonlinear programming, which is solved for the saddle point (Takayama and Judge 1971). In this case the objective function is a quadratic function constrained by linear inequalities, a problem that has a unique solution (Takayama and Judge 1964).

The major assumptions and the economic environment are as follows. A given country is divided into n regions. Each region is represented by one base point at which the supply of primary product, the demand for the final products, and the processing capacity are assumed to be concentrated. All possible pairs of regions are separated by known transportation costs per physical unit for each product. The processing capacity in each region is assumed to be unlimited. Processing is performed at per unit costs that are assumed to be given for each region (from above). Demand for each of the final products is assumed to be known for each region and to be a logarithmic function of price.[5] For each of the n regions a nonnegative quantity of the primary product is given.

In this environment it is possible to formulate a model that accounts for the interaction of the spatially separated economic units. The model determines the level and location of processing of the primary product into final products, gives volume and direction of all product flows that will minimize the aggregate transportation and processing cost, and finally determines the pricing system of all products that accompany the optimum allocation system.

Regional demands for final commodities Y are assumed to be represented by functions dependent on price P. These are of the general form $P = aY^{-b}$. Their tangents represent linear demand functions for the final products in each region. By applying the familiar technique of formulating the "net" social benefit function as the sum of the line integrals of individual demand relations minus the total costs of processing and transportation, a quadratic spatial equilibrium problem can be set up (Takayama and Judge 1971). The objective of this problem is to maximize the "net" social benefit subject to a set of constraints on primary commodity allocation and flows; final commodity production, flows, and consumption; and processing and joint production. All prices and quantities are restricted to be nonnegative.

If the assumptions of the net benefit function and the constraints are satisfied, then a necessary and sufficient condition for an optimum solution to the problem is that the corresponding Lagrangian forms a saddle point. The appropriate Kuhn-Tucker conditions ensure that the solution is a maximum (Takayama and Judge 1964).

Combination of the Model Parts

When the two models are applied jointly, it is assumed that interregional flows take place between regional centers (reference points), while in reality, of course, shipments would flow from all plant centers or local assembly points (in case unprocessed raw products are shipped) to consumption centers. This assumption is justified because it implies realistically that the sum of the costs of all shipments between all pairs of plant centers and assembly points in region i and consumption centers in region j does not, or only to a negligible extent, differ from the costs of shipment between the regional centers of regions i and j.

In combining the two parts of the model into

[4] This functional form is suitable for estimating average cost functions of production processes where economies of size imply that with increasing capacity processing costs are asymptotically approaching a minimum value.

[5] For programming purposes this nonlinear function is assumed to be represented by its linear tangents. The incorporation into the model of the procedure for selecting the representative tangents is described in note 6.

one spatial equilibrium model, the following concept is applied. Assume that there are two systems that are mutually dependent in that the output of one constitutes part of the input of the other. Then, as these systems are optimization models, they form a combined equilibrium model. Their interdependence generates a sequential set of objectives and restrictions, the objective of the plant location model forming a restriction to the interregional trade model and the objective of the interregional trade model forming a restriction to the plant location model. In other words, for each of the two models the optimum solution is to be found subject to the constraint that the other model be optimized. Since part of the input of the model is generated by the other model, a sequence of alternating applications of both models—one in the objective, the other in the constraint, and vice versa—asymptotically approaches an equilibrium solution.[6] We assume that the solution is unique because each of the two parts of this model has a unique solution. Application of the model with empirical data showed consistent convergence of these solutions.[7]

[6] The spatial equilibrium model consists of the following programs: (*a*) quadratic programming model (*QP*), (*b*) single-equation plant location model (*SE*), (*c*) derivation of regional demand functions from a tangent to the exponential demand function (*DT*), and (*d*) testing of the tangent for representativeness and if rejected finding new tangent (*TT*). In applying these programs in the empirical case given below. The most efficient sequence was found to be

$$\begin{matrix} SE_1 \searrow \\ \quad QP_1 \rightarrow SE_2 \rightarrow QP_2 \rightarrow TT_1 \rightarrow QP_3 \rightarrow SE_3. \\ DT_1 \nearrow \end{matrix}$$

[7] The uniqueness of the solution depends upon the character of the set of the various parameters included. In the unlikely but conceivable case in which the parameters included generate nonconvergence of the results (e.g., when the sum of the costs of transportation of the raw materials equals the sum of the costs of the transportation of the final commodities), there would be no unique optimal solution to the problem. By submitting the model to appropriate sensitivity tests, the likelihood of such cases can be evaluated.

An Empirical Application

While there is a sophisticated oilseed processing industry established in India, soybean production, processing, and consumption is a new developing sector in this country. After their introduction in the late 1960s, cream-colored varieties of soybeans covered about 10,000 hectares in 1970–71 and about 43,000 hectares in 1973–74. In 1974, five solvent-extraction plants with a total capacity of 265 tons per day and five screw-press-expeller plants with a total capacity of 11 tons per day were reported to be processing soybeans in India (see table 1).

In view of this development it seems worthwhile to review the results that were generated in 1971 by the above spatial equilibrium model of a future Indian soybean economy based on data collected in 1970–71 (von Oppen 1972). The following is a summary of the major assumptions made on supply demand, transportation, and processing of soybeans (von Oppen 1972, 1974).

Based upon certain agronomic assumptions about the general production potential for soybeans in India, about the extent to which a selected number of crops and fallow land might be substituted by soybeans, and about

[a] One extrusion cooker and one soymilk plant, both still in the experimental stage.

yield, the potential production of soybeans by districts was computed (see figure 2); coterminous districts of homogeneous potential production densities were grouped into seven regions and the share of each region in the total potential production was calculated.[8]

The two joint products, soymeal and soyoil, were assumed to be substitutes for gram flour and groundnut oil, respectively, for each of which demand functions were fitted using time-series data on prices, quantities consumed per capita, and income per capita. The per capita demand for gram flour was estimated, and after conversion into the required form it became

$$P_g = 1.5716\ Y_g^{\ -0.84048},$$

where P_g = price of gram in rupees per kilogram and Y_g = the quantity of gram consumed in kilograms per capita.[9]

The per capita demand for groundnut oil used by the vanaspati[10] industry was estimated, and after conversion into the required form it became

$$P_o = 0.001955\ Y_o^{-1.8298},$$

where P_o = the price of groundnut oil in rupees per kilogram and Y_o = the quantity consumed in kilograms per capita.[11] The demand functions entered into the model were defined as tangents uniquely representing these exponential functions. Regional demands were then derived by dividing the slope of the soymeal demand by regional population, by dividing the slope of the soyoil demand from the vanaspati industry by regional population proportional to vanaspati industry prevailing in each region, and by adjusting the intercept of the soyoil demand function according to the postulated per capita income.[12]

The average costs of processing in solvent extraction plants were estimated from engineering data and found to be $T_3 = 59.95 + 1383.5\ S^{-1}$.[13] Assembly of soybeans from the farmer to the plant and distribution of soymeal from the plant to the consumers was assumed to be carried out by truck; truck rates were found to be a linear function of distance. The intraregional transport was assumed to be carried out by rail according to freight rates for the different commodities in 1970–71.

Table 2 summarizes the major assumptions made with respect to time. The years 1970–71, 1973–74, 1978–79, and 1988–89 are labeled model years A, B, C, and D, respectively. Estimates of the Indian population are taken from official sources. Estimates of income per capita are based on an average annual income between 1964 and 1969 and a compound growth rate of 2% annually during the entire period is assumed. Table 2 also gives the most recent data available on the actual development in 1971 and 1973.

Comparison of the actual development with the model years indicates that in 1973 population, income, and soybean production have developed about three years past the model year A and are about five years "away" from model year B. Therefore, the results (table 3) for model years A and B should be comparable with the actual location and size of soybean processing plants; if so, the results for the later model years C and D would allow one to draw useful conclusions.

Average processing capacity of soybean solvent extraction plants was calculated by the model to grow about 50 tons per day in year A to about 140 tons per day in year B, eventually reaching up to 350 to 400 tons per day in year D. Present capacities of the five solvent extraction plants for soybeans of 53 tons per day seem to be quite in line with this result, even though they range from 10 to 125 tons per day (table 1).

The existing processing plants are located in regions 2, 4, 6, and 7, which is partly in line with our predictions. In contradiction to the

---

[8] Formulation of the interregional trade of a soybean economy (one raw product, two final products) into a quadratic programming model as specified above requires a matrix for n regions of $n \times 7$ rows and $n \times 23$ columns. Seven regions were chosen because on the one hand a larger number of regions would have required excessive computational costs and on the other hand less than seven regions would not have allowed a satisfactory division of the country into reasonably homogeneous areas.

[9] The function was estimated by using seventeen years of All-India per capita net availability and annual average prices of gram (Government of India 1968, 1970, and 1973). The standard error of the exponent is 0.1812, the coefficient of multiple correlation is 0.76, and the F-ratio is 21.5.

[10] Vanaspati, hydrogenated vegetable oil, is commonly used as cooking margarine in India.

[11] The estimation was based on monthly observations for five years (1964 to 1969) on per capita groundnut oil consumption (Q_o), groundnut oil prices (P_o), and per capita income expressed in vanaspati consumption per capita (V_c) (Government of India 1964 to 1969). After adjusting for an autocorrelation of 0.6, the logarithmic function fitted gives

$$\ln Q_o = \underset{(0.4004)}{-0.8590} - \underset{(0.2213)}{0.5465} \ln P_o + \underset{(0.254)}{0.653} \ln V_c.$$

Standard errors are given in parentheses. The coefficient of multiple correlation is 0.37 and the F-ratio is 5.3.

[12] Division of the slope of the soymeal demand by population implies multiplication of the per capita quantity and thus aggregation of the demand function.

[13] Where S represents annual capacity in tons, note that $S = QN^{-1}$.

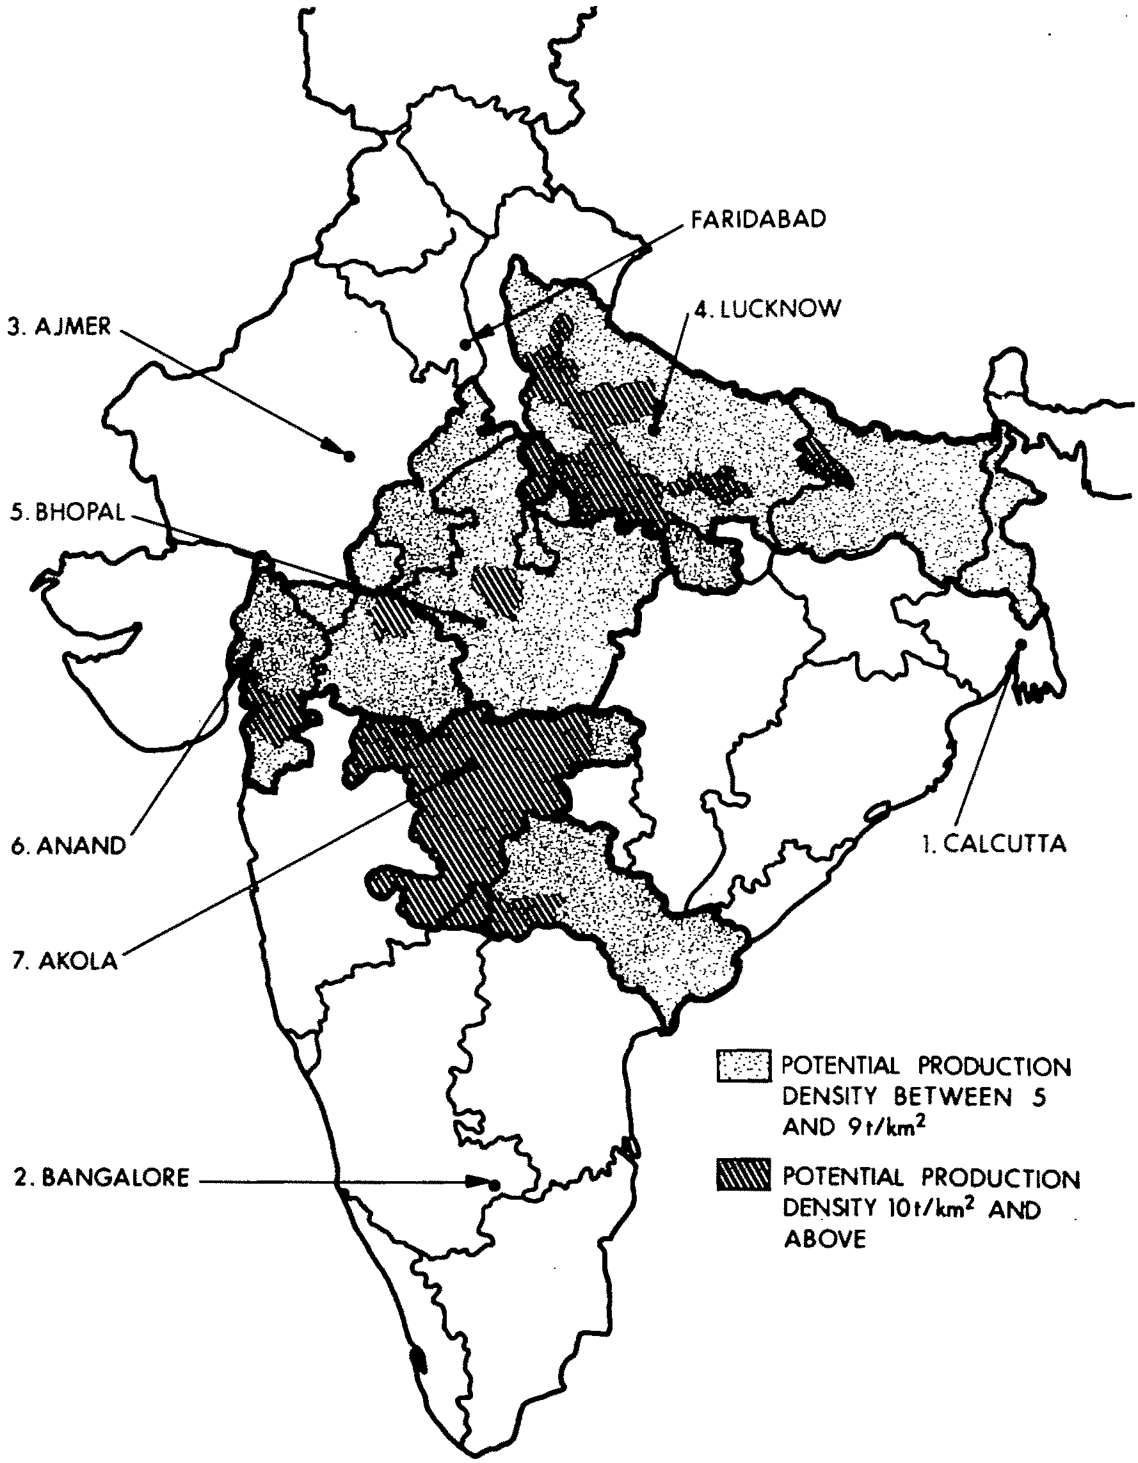

Figure 2. Estimated soybean production potential and demarcation of regions and reference points in India

model result, there is no processing capacity for soybeans in region 5 as yet, while in region 2 soybeans are processed. This can probably be explained by the fact that a reclassification of rail rates in 1973 resulted in a reduction of the rates for soybeans and a substantial in-

[a] Assuming yields are 1 ton/ha.

crease in the rates for soymeal and in making soybean processing feasible also in non-producing regions such as region 2.[14]

Without entering into further discussion of the many reasons why or why not reality differs from the model results in some cases, it can be concluded from the evidence gathered so far over the short period of three years that the soybean economy in India appears to be generally allocating plant capacities and sizes in line with the optimality criteria developed in the model. It should be mentioned here that for several years plans existed to establish one single government-operated processing plant with an initial capacity of about 100 tons per day and a provision to later step up the capacity. This plant was planned to be located in Faridabad, south of New Delhi (Rathod and Motiramani 1974). If only one plant had been available to process the quantities of model years A and B so that interregional trade would have been forced to move soybeans to Faridabad and if soyoil and soymeal were distributed among regions according to the quantities demanded in model years A and B, then this arbitrary solution would have cost the soybean economy in year A about 130% and in year B about 186% of the costs for the optimum solutions (see table 4).

It should be emphasized that starting a soybean economy in India imposes the "chicken-and-egg" problem of simultaneously developing raw material production and processing facilities. If left to itself, this problem will probably be solved by an industry that especially in the initial stages is expanding at very low rates and at the costs of likely mistakes resulting from trial and error approaches. However, with the help of a tool such as the above, despite its many limitations some of the major principles involved in the spatial allocation of the soybean processing industry are recognized and can be applied for future planning by both public and private decision makers in order to foster the growth of the soybean industry.

[14] The ratio of the sum of the costs of transporting soymeal and soyoil over the sum of the costs of transporting soybeans increased from 0.52 in 1970–71 to 0.75 after 1973.

[b] Assuming one plant in each production region with capacities as indicated: region 4: 25 tons/day, region 5: 15 tons/day; region 6: 10 tons/day; and region 7: 20 tons/day, i.e., in total, 70 tons/day.
[c] Assuming average processing costs as indicated in table 4.
[d] Assuming one plant with a capacity of 70 tons/day.
[e] Assuming one plant with a capacity of 1,333 tons/day.

Conclusion

With the aim to contribute to the integration of location theory and of interregional trade theory, a model for plant location and interregional trade was developed. Application of the model on data relevant to a projected soybean industry in India produced feasible results. There is evidence that the actual development in the soybean processing sector up to 1974 has followed the earlier projected path fairly closely. It can be shown that an arbitrary plan of processing soybeans in one single plant located in a consumption region would raise costs to the industry 30% above the optimum level for 1970–71 and 86% above the optimum level in 1978–79. Application of the spatial equilibrium model for plant location and interregional trade may help decision makers to recognize the principles involved in the spatial allocation of agriculture-based processing industry and thereby reduce costs and time required for its development.

Impact of Dryeration on Grain Elevator Performance in a Fluctuating Energy Situation

John B. Penson, Jr., and Bruce A. McCarl

The dryeration process was originally advanced by agricultural engineers to improve grain quality by reducing stress cracks to the kernel normally incurred in the conventional drying process. This study demonstrates that the country grain elevator with dryeration facilities also uses substantially less energy to dry the same amount of grain and achieves higher profits above variable costs associated with drying operations than the elevator with conventional drying facilities, regardless of grain moisture conditions. These advantages are shown to be further magnified if energy prices continue to rise or if potential energy shortfalls are realized.

Key words: elevator profits, energy savings, price rationing, quantity rationing.

The drying function performed by country elevators is a particularly vital service provided to the production and distribution sectors of the nation's food and fiber system. Because this drying function requires large amounts of energy, any disruption to elevator energy supply can in turn result in major disruptions to the remainder of the food and fiber system. Similarly, a significant upward shift in the price of energy may force elevator management to either lower the price they pay for grain or accept lower returns on their investment.

Many experts have raised the spectre of major energy shortfalls in the near future. The U.S. Geological Survey, for example, recently cut by more than one-half their earlier estimates of undiscovered recoverable petroleum and gas reserves in the United States. President Ford, in his 1975 State of the Union Message, advocated raising the domestic price of energy to discourage consumption and encourage domestic production by imposing an import tax on foreign oil and decontrolling domestic "old" oil prices. The individual grain elevator facing either energy shortages or price increases must be prepared to implement energy conserving management strategies that allow for continued receipt and processing of desired grain throughout. One particular management strategy that appears to conserve considerable energy, thereby increasing profits, is the installation of dryeration facilities in the elevator's configuration.

The purpose of this paper is to examine the potential savings to a country grain elevator from adopting dryeration facilities rather than conventional drying facilities. To accomplish this, operations of two alternative elevator configurations that utilize different drying facilities are simulated in accordance with an experimental design. Functions explaining the amount of energy use associated with the quantity of grain dried for each alternative drying facility are then estimated based on these experiments. Finally, a decision model reflecting elevator management behavior under alternative market situations is used to illustrate potential elevator response to selected energy situations.

Alternative Elevator Configurations

A dynamic simulation model of a typical midwest grain elevator developed and validated originally by Deason was used in this study to

simulate elevator receiving and processing operations over time in a weather-dependent environment. This model was recently modified and updated by Uhrig and McCarl. Figure 1 presents a flow chart that depicts the overall structure of the simulation model and the information it provides.

Monte Carlo methods, using direct transformation of uniform random deviates, are used in the model to obtain values for such stochastic elements as load size, moisture content, and daily arrival pattern. The elevator's performance is dependent upon its designed capacity, the length of the harvest season, its location, weather conditions, and the nature of its drying facility. Once these elements are specified, the simulation model determines daily arrivals and drying schedules using the "first-in–first-out" principle for processing grain receipts.[1]

Two experiments were conducted with this simulation model to determine an elevator's grain drying response surface under alternative elevator configurations. The first experiment focused on the response surface for an elevator using conventional drying facilities, while the second experiment focused on an elevator's response surface when dryeration facilities are adopted. The simulation model was programmed to report the amount of grain dried for every 2,500 gallons of liquid propane equivalent used for each elevator configuration.

Conventional Drying Facilities

Conventional drying facilities, as defined in this study, require grain to be dried to the final desired moisture content and cooled in the dryer. The overall elevator configuration includes wet aerated storage facilities to level out the receipts pattern, thereby allowing the dryer to operate during hours of no receipts. For the purposes of this study, this experiment is designed to reflect two annual elevator capacities: 1.0 and 1.5 million bushels, respectively. The harvest season is assumed to be forty-five days long and the location examined is central Indiana. Weather variability is based upon five years of data from the U.S. Weather Bureau covering the 1959–63 period. The elevator is designed to have a dryer capable of removing five points of moisture from 2,500 bushels per hour and is supported by 20,000 bushels of temporary storage and 100,000 bushels of wet aerated storage. Finally, the elevator is designed to have a 600 bushel dump pit and a 7,000 bushel per hour leg. The mean load size, a stochastic element in the simula-

[1] The grain elevator simulation model developed by Deason was specifically designed to reflect the physical operation of a country grain elevator. As such, the model, which was exhaustively validated, is ideally suited to examining the effects of alternative elevator configurations on physical throughput. For additional description of the properties and validation of the simulation model, see Deason or Uhrig and McCarl.

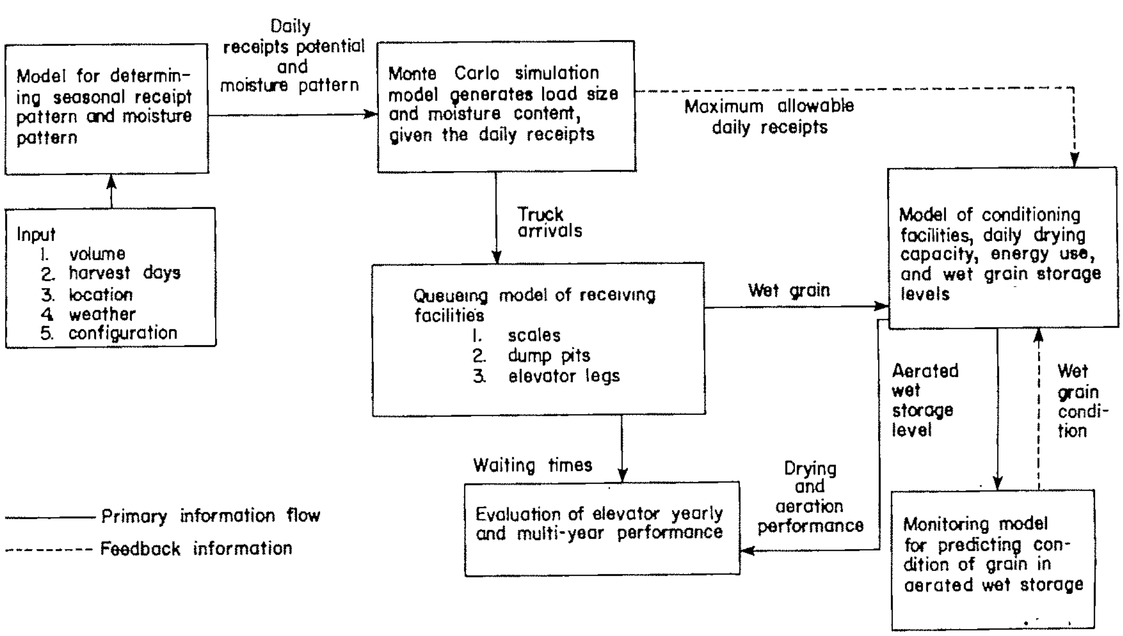

Figure 1. Structure of elevator model and informational flow (adapted from Uhrig and McCarl)

tion model, was 21,000 pounds and was normally distributed with a standard deviation of 6,000 pounds.[2] The mean scale service time was 1.8 minutes and was also normally distributed with a standard deviation of 0.25 minutes.

Each of the trials within the experimental design was simulated under the above conditions for a five-year period. This procedure was then repeated for two additional sequences of random numbers to test the hypothesis that there was a significant difference in the grain drying response surfaces exhibited by each of the three random samples. The results of this experiment are examined in the next section of this paper.

Dryeration Facilities

The above experiment was repeated for an elevator configuration that utilized dryeration rather than conventional drying facilities. Dryeration, as reported by McKenzie et al., involves a regular high speed, high temperature drying facility with a slow cooling process. Unlike conventional drying facilities, no cooling is done in the dryer. Rather, grain is discharged from the dryer while it is still hot and still carrying excess moisture (one to three points above the final desired moisture content) and is loaded into an aerated cooling bin. The grain is stored without aeration for anywhere from four to ten hours for tempering. Finally, the grain is cooled slowly by moving air upward through the bin. The first grain put in the cooling bin will be the first cooled. This slow cooling stage takes approximately ten hours, requires very little energy, and reduces the moisture content about two points. The grain is then unloaded, cool and dry.

Dryeration, according to McKenzie et al. as well as the Council for Agricultural Science and Technology (CAST), not only reduces the occurrence of stress cracks to the kernel normally associated with conventional drying facilities but increases dryer output by 60% for ten points of moisture removed. Furthermore, they suggest that dryeration increases fuel efficiency by 20% to 30% over conventional drying facilities. The impact of the installation of dryeration facilities was accounted for in the simulation model by adjusting the elevator's dryer capacity accordingly.[3]

Determinants of Energy Needs

The following functional form was estimated for each elevator configuration based upon the response surfaces reported by the simulator for each of the above experiments:

$$(1)\quad EU_i = B_{oi} + B_{ei}GR_i + B_{zi}GR_i[Dez] + B_{mi}GR_i[Dhm] + B_{xi}GR_i[Dez][Dhm] + u_i, (i = d, cd),$$

where EU_i = gallons of liquid propane equivalent used to dry grain associated with the ith elevator configuration, GR_i = bushels of grain dried associated with the ith elevator configuration, Dez = 0, 1 dummy variable for alternative annual elevator capacities (1.0 and 1.5 million bushels), Dhm = 0, 1 dummy variable for high moisture conditions (field moisture content greater than 20% at harvest), u_i = random error term associated with the ith configuration, d = elevator configuration with dryeration facilities, cd = elevator configuration with conventional drying facilities.

In both instances, one would expect a positive sign on the B_{ei} coefficient since increases in the quantity of grain dried will require additional energy use. The sign on the B_{zi} coefficient should be negative if elevators become more efficient in their energy use as elevator size increases, other things being constant. The sign on the B_{mi} coefficient is expected to be positive since more moisture removal will necessitate a longer drying time and thereby increase the elevator's energy use for a given amount of grain throughput. The final coefficient, B_{xi}, which reflects the interaction between elevator size and grain moisture, should be negative if the increase in

[2] The hypotheses that load size and moisture content are normally distributed were accepted by Deason based upon the Kolmogorov-Smirnov test for goodness of fit.

[3] Dryer capacity for conventional drying facilities, according to Klein, McCarl, and Peart, is given by

$$DC_{cd} = D_{cd}/[-2.35 + 0.169M_{cd}],$$

where DC_{cd} = conventional dryer capacity, C_{cd} = the bushel per hour capacity of the dryer for five points of moisture removal, and M_{cd} = the moisture content of the grain. For dryeration facilities, dryer capacity is given by

$$\begin{aligned} DC_d = DC_{cd}[1.0 + [[M_d/(100 - M_d)] \\ - [M_{cd}/(100 - M_{cd})]]100]/[[WM/(100 - WM)] \\ - [M_{cd}/(100/M_{cd})]]100, \end{aligned}$$

where WM = the net basis moisture content of grain dried. If M_d = 17.5, M_{cd} = 15.5, and WM = 21.0, the dryer capacity would increase by 34.8% if dryeration facilities were adopted.

energy use under higher moisture conditions declines as plant size increases.

The functional form outlined in equation (1) was estimated for each experiment using ordinary least squares regression. A total of 297 observations were available to estimate the equation for regular drying facilities, while 169 observations were available to estimate the equation for dryeration facilities. This difference in sample size was due to the fact that the elevator with dryeration facilities used less fuel in reaching its maximum grain throughput than the elevator with regular drying facilities.

Equations (2) and (3) below present the results from the estimation of the coefficients of a modified specification of the functional form given in equation (1). Earlier tests show that the B_{zi} and B_{xi} coefficients in equation (1) were not significantly different from 0 at the 10% level:

$$(2) \quad EU_{cd} = 0.01266 + \underset{(0.0023)}{0.0432}\, GR_{cd} + \underset{(0.0022)}{0.0567}\, GR_{cd}[Dhm],$$

and

$$(3) \quad EU_{d} = 0.0085 + \underset{(0.0039)}{0.0393}\, GR_{d} + \underset{(0.0036)}{0.0339}\, GR_{d}[Dhm].$$

The figures in parentheses are standard errors. The coefficient of determination adjusted for degrees of freedom associated with equations (2) and (3) were 0.893 and 0.924, respectively.[4] In both instances, the signs on the b_{ei} and b_{mi} coefficients confirm our earlier hypotheses.[5] In addition, both sets of coefficients were significantly different from 0 at the 1% level. Finally, the b_{ecd} and b_{mcd} coefficients were significantly different from the b_{ed} and b_{md} coefficients, respectively, at the 1% level.[6]

The b_{ei} and b_{mi} coefficients corresponding to the GR_i regressor indicate that an increase in grain drying will require larger amounts of liquid petroleum equivalent for those elevators with conventional drying facilities than for those with dryeration facilities. The reciprocals of the b_{ei} and b_{mi} coefficients in equations (2) and (3) express the effect that an additional gallon of liquid petroleum equivalent can have on the quantity of grain dried, other things being equal. Under low grain moisture conditions (field moisture less than 20%), for example, one gallon of liquid petroleum equivalent was estimated to dry 23.1 bushels of grain at an elevator with conventional drying facilities versus 25.5 bushels at an elevator with conventional dryeration facilities. The b_{ei} and b_{mi} coefficients together indicate that, under higher grain moisture conditions (field moisture greater than 20%), the elevator with conventional drying facilities will dry 11.0 bushels of grain per gallon of liquid petroleum equivalent versus 13.7 bushels if the elevator configuration instead utilizes dryeration facilities. Thus, the elevator with dryeration facilities can dry 10% more grain per gallon of liquid propane equivalent under low grain moisture conditions than the elevator with conventional drying facilities.[7]

Based upon the above empirical results, an analysis of the impact that energy shortages or quantity rationing of energy can have on the performance of a country grain elevator is seemingly straightforward. The quantity of grain dried under alternative grain moisture conditions and energy use levels for elevators with and without dryeration facilities was determined above by expressing equations (2) and (3) in terms of the quantity of grain dried. Yet Federal Energy Administration allocation rules at the time of the Arab oil embargo and those that remain in abeyance at present suggest that the food and fiber system would have top priority in any quantity rationing scheme. Instead, price rationing seems equally, if not more, likely. To determine the potential effect that price rationing can have on the performance and profits of an elevator with or without dryeration facilities, we must propose a model that reflects potential elevator management behavior.

---

[4] Earlier tests showed that a double log transformation of equation (1) led to a slightly lower coefficient of determination for each elevator configuration than that reported for equations (2) and (3).

[5] The estimated values for the B_j coefficients (j = 0, 3, and m) are hereafter referred to as b_j coefficients to distinguish between the population parameters and the OLS parameter estimates.

[6] A comparison with estimates based on repeated random samples suggests that we not accept the hypothesis that there is a significant difference in the response surfaces implied by different random samples. The estimates of bushels of grain dried per gallon of energy use are based on grain moisture at harvest during the 1959–63 period in central Indiana. The pounds of water removed and hence amount of energy required are influenced by these moisture levels. Weather data for other time periods may slightly alter the regression estimates.

[7] The CAST suggest that dryeration decreases fuel needs by 20% to 30%. Since corn is typically harvested in the midwest at a moisture content substantially higher than 20%, the 25% increase in fuel efficiency found under high moisture conditions in this study seems reasonable.

Elevator Decision Model

The following model reflects the decision-making framework of elevator management that must pay the farm firm a price for grain (PP_g) that is an increasing function of the quantity it purchases. We shall assume that elevator management is a price taker in its other factor markets and its product market. This assumption permits us to treat the price paid for energy (PP_e), elevator handling costs (HC_i), and the price received for processed grain (PR_g) as given. We shall assume for the purposes of this study that the objective of elevator management is to maximize profits. If PP_g is an increasing function of grain purchases, the elevator will desire to buy grain until the marginal cost of grain purchases equals its marginal revenue product:[8]

$$(4) \quad \max \pi_i = [PR_g - HC_i]GR_i - PP_gGR_i - PP_eEU_i,$$

where

$$(5) \qquad EU_i = b_{oi} + \Phi_{ei}GR_i$$

and

$$(6) \qquad \Phi_{ei} = b_{ei} + b_{mi}[Dhm],$$

subject to

$$(7) \qquad 0 \leq GR_i \leq \theta_{gr},$$

$$(8) \qquad b_{oi} \leq EU_i \leq \theta_{eu},$$

and

$$(9) \qquad PP_g = \delta + \alpha GR^*_i,$$

and where π_i = profit associated with the ith elevator configuration, PR_g = price received by the elevator for grain marketings, PP_g = price paid by the elevator for grain purchases, HC_i = handling costs per bushel excluding drying associated with the ith elevator configuration, b_j = estimated values for the B_j coefficients in equation (1) where $j = o, e,$ and m, PP_e = price paid by the elevator for liquid petroleum equivalent, θ_{gr} = maximum elevator grain throughput, θ_{eu} = maximum liquid petroleum equivalent available to the elevator, and GR^*_i = quantity of grain supplied by the farm firm to the ith elevator configuration.

Equation (5) represents a restatement of equations (2) and (3) for an elevator with and without dryeration facilities, respectively. Equations (7) and (8) account for annual elevator capacity and energy availability constraints. Equation (9) reflects the farm firm's response to the purchase price of grain (PP_g), where price rather than quantity is used as the dependent variable. GR^*_i represents grain sales by the farm firm, while $\alpha\,[GR^*_i/PP_g]$ is the measure of price flexibility.

Two simplifying assumptions are made with respect to the model above. First, we assume that the elevator can get all the energy it needs at price PP_e. This assumption renders the constraint in equation (8) ineffective. Our second assumption is that we can neglect the elevator capacity constraint in equation (7) for the moment. Given these assumptions, we can solve for the equilibrium condition. By substituting equations (5) and (9) into equation (4) and differentiating with respect to GR_i, we see that

$$(10) \quad \frac{d\pi_i}{dGR_i} = PR_g - HC_i - PP_e\Phi_{ei} - [\delta + 2\alpha GR_i),$$

where

$$(11) \qquad \frac{d^2\pi_i}{d\,GR_i^2} = -2\alpha.$$

The last term in equation (10) represents the marginal cost of grain purchases to the elevator. Where equation (10) is equal to 0 and equation (11) is less than 0 (i.e., α is positive), elevator profits are at their maximum.

We can now set equation (10) equal to 0 and solve for the desired level of grain dried. This quantity, expressed in millions of bushels, is given by

$$(12) \quad GR_i = \left[\frac{PR_g - HC_i - \delta - PP_e\Phi_{ei}}{2\alpha}\right],$$

where $0 \leq GR_i \leq \theta_{gr}$. By substituting the value for GR_i obtained from equation (12) into equations (5) and (9), we can determine the desired level of energy use and the price paid for grain, respectively. Finally, elevator profits above variable costs associated with drying activities are determined by substituting the values for GR_i, EU_i, and PP_g into equation (4).

In order to complete the model, we must determine values for δ and α in equation (9). We shall examine the effect that two hypothesized input supply elasticities that reflect al-

[8] In the event that there are many elevators serving the local grain purchase market, the individual elevator will instead maximize producer plus consumer surplus. By integrating under the curves and solving for GR_i, it can be shown that the denominator in equation (12) would equal α rather than 2α. Solutions of the model under these conditions show that the elevator with dryeration facilities has a competitive advantage; it can pay more for grain and stand a much higher price for energy regardless of level of grain moisture.

ternative assumptions regarding the degree of competition the elevator faces in the grain purchase market has on its performance and profits. The first elasticity is one that approaches infinity ($\xi_p \to \infty$), reflecting the micro "perfect competition" assumption that an elevator has little or no influence on PP_g. The second elasticity of 5.0 allows for more elevator influence on PP_g.[9]

The model accounts for the performance and profits of a country grain elevator when the price of energy is exogenously altered. In the case where the supply of energy to the country grain elevator is limited due to, say, quantity rationing (i.e., $EU_i = \theta_{eu}$), other things being constant, the quantity of grain dried will be given instead by

$$GR_i = 1/\Phi_{ei}[-b_{oi} + \theta_{eu}], \tag{13}$$

where $0 \leq GR_i \leq \theta_{gr}$.

By assuming values for PR_g, PP_e, and HC_i, we can now use the elevator decision model to illustrate the potential magnitude of an elevator's response to selected energy situations for elevator configurations with and without dryeration facilities.

Potential Savings from Dryeration

Table 1 presents the desired quantities of energy use and grain dried for a country grain elevator with and without dryeration facilities for those values of PR_g, PP_e, and HC_i assumed in this study. The model solutions presented reflect the effect of low and high grain moisture conditions for two hypothesized input supply elasticities.

If grain moisture at harvest is less than 20%, there is only a slight economic advantage to elevator management investing in dryeration facilities. Depending on the degree of competition in the grain purchase market, elevator profits above variable costs associated with drying operations will be 1% to 3% higher with dryeration facilities. This increase in profits is a direct result of the 14% to 16% increase in fuel efficiency. It is interesting to note that if the input supply elasticity is 5.0, the elevator with dryeration facilities will actually prefer to dry 0.2% less grain than it would otherwise because of higher handling costs.[10] Further, the value for PR_g would have to reach \$2.80, other things being constant, before either elevator configuration would be operated at full capacity.

If grain moisture at harvest is more than 20%, there is a decided economic advantage to the elevator management that invests in dryeration facilities. Depending again on the degree of competition the elevator faces in the grain purchase market, elevator profits above

[9] When $\xi_p \to \infty$, $\alpha \to 0$, that is, the elevator's marginal cost of purchasing grain $PP_g[1 + (1/\xi_p)] = \$2.25$. The values for α and δ for both elasticities are based upon a price of \$2.25 and a quantity of 1 million bushels.

[10] The operation of dryeration facilities requires an additional handling cost of \$1 per dryer load from running the cooling fan and handling equipment to load and unload the bin. This charge is based on \$0.06 per kilowatt-hour for power and 2,500 bushels of grain dried per day. Thus, a \$0.003 per bushel charge must be added to the handling cost of \$0.08 per bushel incurred with conventional drying facilities. Since the dryeration facilities are fully automated, there is no additional labor charge.

Table 1. Comparison of Optimal Solutions for a One Million Bushel Country Grain Elevator

Item	Dryeration Facilities		Conventional Drying Facilities		Percentage Change from Conventional Drying Facilities[a]	
	$\xi_p = 5.0$	$\xi_p \to \infty$	$\xi_p = 5.0$	$\xi_p \to \infty$	$\xi_p = 5.0$	$\xi_p \to \infty$
			Low Grain Moisture			
GR_i (mil. bu.)	0.663	1.000	0.664	1.000	−0.21	0
EU_i (mil. gal.)	0.035	0.048	0.041	0.056	−16.20	−14.34
PP_g (\$/bu.)	2.098	2.249	2.099	2.249	0	0
π_i (mil. \$)	0.194	0.146	0.193	0.142	0.73	2.82
			High Grain Moisture			
GR_i (mil. bu.)	0.644	1.000	0.633	1.000	1.83	0
EU_i (mil. gal.)	0.056	0.082	0.076	0.113	−26.52	−27.38
PP_g (\$/bu.)	2.090	2.249	2.085	2.249	0.25	0
π_i (mil. \$)	0.183	0.129	0.174	0.114	4.93	13.59

Note: These results are based upon solutions where $PR_g = \$2.50$, $PP_e = \$0.50$, $HC_d = \$0.083$, and $HC_{cd} = \$0.08$ per unit. The values for δ and α in equation (9) for both supply price elasticities examined in this study are based upon a price of \$2.25 paid for grain (PP_g) and a quantity of 1 million bushels supplied.

[a] Computed from unrounded data.

variable costs will be 5% to 14% higher under dryeration. If the elevator with dryeration facilities faces an input supply elasticity of 5.0, it will dry almost 2% more grain and yet use 26.5% less energy. Both elevator configurations would require a value of $2.82 for PR_g before they would choose to operate at full capacity. If, on the other hand, both elevators face an input supply elasticity approaching infinity, the amount of grain dried will be limited by the 1 million bushel annual elevator capacity assumed in this solution. The elevator with dryeration facilities, however, will use 27.4% less fuel to dry the same amount of grain.

Effects of Alternative Energy Solutions

The purpose of this section is to extend further our analysis of the potential savings from the adoption of dryeration facilities by examining the impact that selected quantity and price rationing schemes can have on the performance and profits of a country grain elevator.

Quantity Rationing

Quantity rationing of energy, other things being constant, can have only one of two possible effects: it will be ineffective where the quantity required is less than the quantity rationed (i.e., $EU_t < \theta_{eu}$), or it will limit the elevator's performance and profits (i.e., $EU_t = \theta_{eu}$). We shall assume that quantity rationing of energy to a country grain elevator is a feasible policy alternative and that the elevator was previously operating at the point where profits above variable costs were maximized (see table 1). Alternative solutions of the elevator decision model in which previous energy use associated with drying operations is reduced by 10% and 20%, respectively, are shown in table 2.

A comparison of tables 1 and 2 shows that an elevator facing an input supply elasticity approaching infinity under high grain moisture conditions will suffer a 10% to 12% loss in profits above variable costs if the amount of energy previously used to dry grain is reduced by 10%. If energy supplies are instead reduced

by 20%, elevator profits would decline by 21% to 23%. In both instances, profits above variable costs for an elevator with dryeration facilities would decline by a greater percentage but would still be higher than profits of an elevator with conventional drying facilities. The quantity of grain dried by both elevators would fall by about the same percentage that energy is rationed.

If the elevator under high grain moisture conditions instead faces an input supply elasticity of 5.0, it will pay 1.4% less for grain if the 10% quantity rationing scheme is employed and 2.8% less if the 20% scheme is used. Because of these lower values for PP_g, profits of an elevator with dryeration facilities would now decline by a smaller percentage than profits of an elevator with conventional drying facilities. While the quantity of grain dried still falls by about the same percentage that energy is rationed, it is interesting to note that an elevator with either drying facility in a year of high grain moisture would operate at one-half capacity if energy supply is cut by 20%.

Price Rationing

Unlike the quantity rationing schemes, we shall now assume that the elevator can get all the energy it needs at a value for PP_e determined by a price rationing scheme. Two such price rationing schemes are examined here for their effect on elevator performance and profits. Alternative solutions of the elevator decision model in which the previous value for PP_e of \$0.50 including tax is increased by \$0.25 and \$0.50, respectively, are presented in table 3.

A comparison of tables 1 and 3 shows that an elevator with dryeration facilities operating under high grain moisture conditions and facing an input supply elasticity approaching infinity would suffer a 15.5% loss in profits above variable costs if PP_e was increased to \$0.75. The profits of an elevator under the same moisture conditions with conventional drying facilities would decline by 24.6%. If PP_e were instead increased to \$1, the elevator under the above conditions with dryeration facilities would see its profits above variable

costs decline by 31.8%, while the elevator with conventional drying facilities would suffer a 49.1% decline. Importantly, the amount of energy used by either configuration in which the input supply elasticity approaches infinity would not change despite the higher values for PP_e.

Although the elevator confronted by an input supply elasticity of 5.0 will experience smaller declines in profits, it will also use less energy and dry less grain. A comparison of tables 1 and 3 indicates that an elevator with dryeration facilities under high grain moisture conditions will reduce its energy consumption by 3.6% when PP_e is increased to \$0.75 and 5.4% when PP_e is increased to \$1. Accordingly, the quantity of grain dried would decline by 3.1% and 6.2%, respectively. If the elevator was instead equipped with conventional drying facilities, its energy use would decline by 4.0% and 7.9% and the quantity of grain dried would decline by 4.4% and 8.9%, respectively.

The Investment Decision

Assuming that the elevator wishes to expand its drying capacity, the choice between dryeration and conventional drying facilities will depend on which has the highest net present value. According to McKenzie et al., the cost of a new dryer is about \$3,000 per 1,000 bushels of daily drying capacity. If dryeration increases the existing dryer's capacity by 60%, a 1,600 bushel dryer coupled with dryeration equipment could handle an additional 1,000 bushels per day. Thus, we want to compare the cost of the dryeration equipment capable of handling a 1,600 bushel dryer to the \$3,000 cost of the new dryer.

The primary cost of converting to dryeration is the investment in a cooling bin, aeration equipment, and additional grain handling equipment to fully automate the facility. A dryer with a 1,600 daily capacity will require a cooling bin large enough to handle a minimum of 2,500 bushels per day to accommodate the 60% increase in dryer capacity. According to McKenzie et al., the cost of a cooling bin runs about \$1 per bushel, while the capital equipment needed to complete the facility costs about \$1,000. Thus, the initial investment cost for the dryeration facilities would be roughly \$500 higher than conventional drying facilities.[11] Ranking of these two investment alternatives will depend therefore on whether the net present value of elevator profit flows over the service life of dryeration facilities is more than \$500 greater than that for regular drying facilities. This assumes that the length of service life, degree of market risk, and salvage values for both facilities are equal. A review of tables 1, 2, and 3 shows that, based upon the prices assumed in this study, this criterion is easily met in areas in which grain is harvested with a moisture content greater than 20%, regardless of whether either of the rationing schemes examined in this study are implemented. The investment decision in areas where grain is normally harvested at lower grain moisture contents may depend on the degree of competition the elevator faces in the grain purchase market and the cost of energy.

Summary and Conclusions

The purpose of this study was to estimate the potential savings a country grain elevator could realize by investing in dryeration facilities. The solutions to the elevator decision model indicate that dryeration leads to higher profit levels over variable costs and a more efficient use of energy than conventional drying facilities, particularly if grain is harvested at a relatively high moisture content. This economic advantage is further magnified if either price or quantity rationing schemes are implemented. In addition to these advantages, there remains the purpose for which dryeration facilities were originally advanced: they reduce the amount of stress cracks to the kernel, thereby increasing corn quality. The recognition of this feature of dryeration in our grading standards for feed grains would result in even higher profit levels above variable costs for the elevator equipped with dryeration facilities and promote a more efficient use of our energy supplies.

[*Received September 1975; revision accepted March 1976.*]

[11] If season-end storage capacity is needed, whether dryeration is used or not, then most of the cooling bin cost can be considered as storage cost rather than dryeration facility cost.

A Sequential Model of the Farm Firm Growth Process

Ying I. Chien and Garnett L. Bradford

Multiperiod linear programming and computer simulation techniques are integrated into a single recursive-sequential model of the farm firm growth process. The model is tied to dynamic theories of the firm's planning behavior first developed by Hicks and more recently by Modigliani and Cohen. A central Kentucky beef farm empirically illustrates predictive features of the model. Three alternative beef production management strategies are compared to demonstrate the model's potential for explaining and predicting alternative farm firm growth processes.

Key words: beef, computer simulation, farm firm growth, linear programming.

Most farm firm growth research of the past twenty years has employed either multiperiod linear programming (MLP), recursive linear programming (RLP), or computer simulation (CS).[1] Potential benefits of such models are impressive, but when used alone each contains shortcomings inherent in the assumptions. The typical MLP model provides a global optimal solution and has other dynamic features but assumes certain knowledge about production and price coefficients and that all inputs and products are perfectly divisible. As demonstrated in previous studies (Martin and Plaxico; Johnson, Tefertiller, and Moore), these assumptions can be relaxed to a limited extent. Johnson, Tefertiller, and Moore, for example, relaxed the certainty assumption by using a Monte-Carlo method to allow variation in yields of crop activities. Heidhues, using an RLP model, was among the first to develop a sequential optimizing procedure to describe how plans for a given time period are related to past entrepreneurial expectations and performances of past plans. Thus, his model contained predictive as well as prescriptive features.

Neither MLP nor RLP models used alone, however, can adequately handle and predict financial variables. Also, it is difficult to incorporate behavioral and qualitative decision variables into programming models. Computer simulation (CS) models can transcend such difficulties and if properly constructed can handle multiple goals, indivisibilities, and sequential decisions (see Hinman and Hutton, Patrick and Eisgruber). Still, CS models used alone tend to lack optimizing features and adequate linkage among time periods in the overall planning process.

These shortcomings can result in substantial gaps between theory and reality. For these reasons, this article is designed to extend and improve existing firm growth modeling techniques by combining desirable features of the MLP, RLP, and CS models into a single computer-based model. The proposed sequential model is based on theoretical constructs discussed briefly in the next section, followed by an outline of the model framework and an empirical illustration.

Theoretical Constructs

Our conceptual framework of the farm firm growth process rests upon theories developed by Hicks and later by Modigliani and Cohen. When combined, these theories take into account dynamic planning behavior of the firm's management and also take into consideration that the model should be capable of implementing farm planning and operations into a real world setting.

In his *Value and Capital*, Hicks developed a dynamic decision-making theory of the firm

Ying I. Chien is an assistant professor of business administration at Morehead State University, Kentucky, and Garnett L. Bradford is a professor of agricultural economics at the University of Kentucky, Lexington.

[1] Irwin's extensive review of the pre-1969 literature (pp. 82–100) is consistent with this classification.

under certainty. According to his view, just as in static theory the firm is to choose from among alternative available courses of action the one that is most conducive to the achievement of its goal. Hicks expressed his idea by arguing that "... the decision which confronts any particular entrepreneur at any date ... may be regarded as the establishment of a production plan ..." (p. 193). He comments further that "... just as the static problem of the entrepreneur is the selection of a certain set of quantities of factors and products, so the dynamic problem is the selection of a certain production plan from the alternatives that are open ..." (p. 194). From this proposition, he concludes that the decision problem faced by the firm at any given point of time is the selection of the best plan over the planning horizon. The most fundamental way of selecting the preferred production plan involving costs and returns in future periods is that of the largest capitalized value from the several streams of surplus. Hicks called it "... their capitalized value of the production plan ..." (p. 195).

The implication of Hicks's formulation is that at the beginning of each period the firm faces an optimization problem, subject to certain constraints over some definite horizon. He also implicitly indicates that definite estimates of parameters associated with these constraints are obtainable through anticipations.

Modigliani and Cohen contend that in reality "economic men" do not generally behave expressly in the way implied by Hicks's concept. They indicate that the discrepancy between the conclusion of Hicks's analysis and observed behavior may be explained in three ways. First, uncertainty is involved in the real world, and the existence of uncertainty tends to shorten considerably the time horizon over which it is useful to form anticipations or to formulate plans. Second, Hicks's model, which assumes rational behavior on the part of business firms, cannot thus adequately account for actual behavior. Finally, they argue "... while it is perfectly true that in terms of the pay-off function the single current move of the static model is replaced by the entire set of moves over the horizon, it does not necessarily follow that, as in the static model, the firm must choose now its entire course of action ..." (p. 20). Therefore, they propose "... the decision problem confronting the entrepreneur at a given point of time is most usefully regarded not as that of selecting the best possible plan of operations over the horizon, but rather, as that of *selecting the best possible first move only*" (p. 20).

The "best possible" not only refers to the first period but refers to the entire optimization problem over the horizon. In this sense, this formulation is similar to Hicks's notion. However, there is a conceptual difference in that their formulation places major stress on the first period of the planning period. It also stresses the point that the decision maker will revise his plans when information becomes available through time, even if he does not have great confidence. Long-run plans are, therefore, not necessarily made up in order to be implemented but mostly to utilize all the available information to make the best plan for the current period.

Overview of the Model

Four recursive phases of farm business planning and implementation comprise the framework of the model (figure 1). Consistent with Hicks's concepts, we argue that at the beginning of each planning horizon the farm firm entrepreneur formulates price and yield expectations in accordance with his goals, the firm's resources, the existing enterprise organization, and financial situation (phase 1). These expectations form a basis for the delineation of an optimal long-run plan (phase 2).

While we accept the essence of Hicks's concept, it is not realistic that any optimum multiperiod plan is likely to be implemented through all periods of the planning horizon. Expectations by definition are *ex ante*, subject to errors. Institutional and political forces are constantly shifting. The entrepreneur continually gains experience and gathers information, even though his psychological inertia tends to inhibit alterations in the plan. Thus, in concert with Modigliani and Cohen, we argue that the entrepreneur formulates a long-run plan primarily to provide for the best possible first move during the current period. Such managerial processes are taken into consideration through the computer simulation submodel, which includes behavioral constraints and the decision-operation process (phase 3).

At the end of each period, the current plan becomes the realized (*ex post*) plan. The farm firm entrepreneur accumulates information regarding the outcome from previous decisions and operations and prepares summary reports.

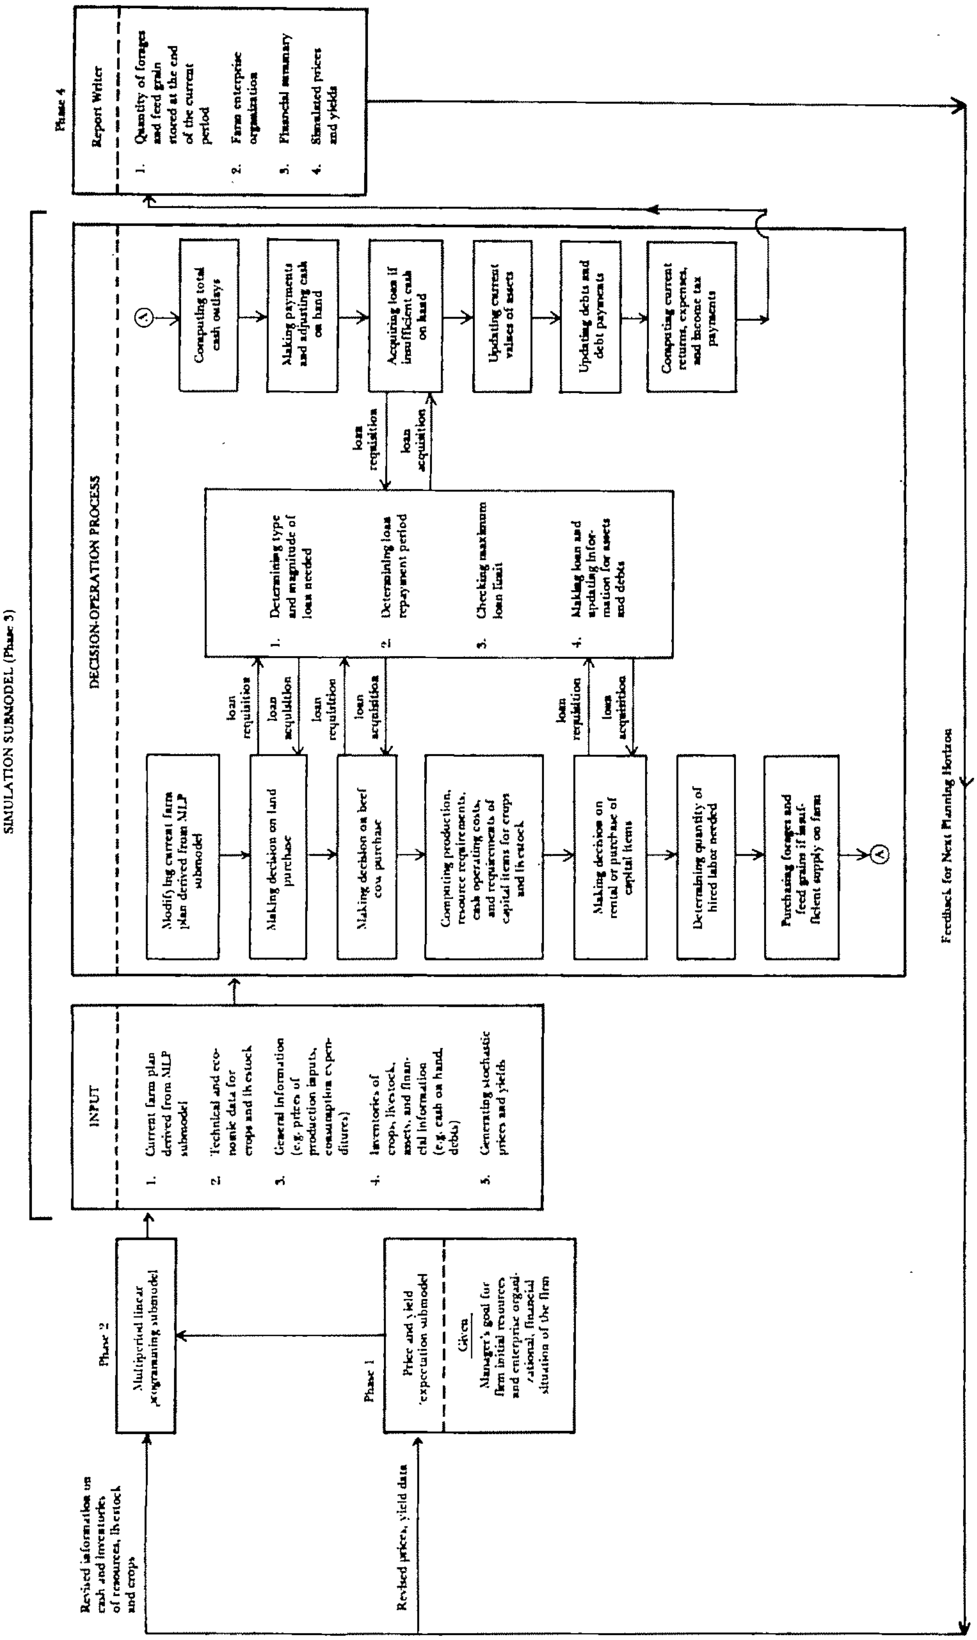

Figure 1. A schematic diagram of the sequential model of the farm firm growth process

With this accumulated (updated) information he then formulates new price and yield expectations and then a new or modified *ex ante* (long-run) plan for the next planning horizon. A time path of this farm firm growth process may be obtained by repeating the sequence of phases over a number of periods.

The Operational Model

The expectation submodel, adapted from Nerlove's distributed lag model (p. 52), is used to quantify the entrepreneur's price and yield expectations (phase 1). Initial expected levels for yields were computed from 1961 to 1965 (USDA). Levels for prices were adapted from Kentucky data (Card and Koepper). Coefficients of expectations were assigned on the basis of "thumb rules" obtained in consultation with agricultural extension specialists for the respective commodities.

The MLP Submodel

Multiperiod linear programming (MLP) is used to approximate the entrepreneur's long-run planning behavior. It is assumed that he will behave as if he made a long-run plan consistent with Hicks's theory underlying the MLP model. Mathematical details of this submodel may be found in Chien and Bradford. A summarized version is

$$\text{(1)}\quad \max \sum_{i=0}^{k} C_{t+i} X_{t+i} \text{ subject to}$$

$$\begin{bmatrix} A_t & & & & \\ & A_{t+1} & & & \\ & & \cdot & & \\ & & & \cdot & \\ & & & \cdot & \\ & & & & A_{t+k} \end{bmatrix} \begin{bmatrix} X_t \\ X_{t+1} \\ \cdot \\ \cdot \\ \cdot \\ X_{t+k} \end{bmatrix} \leq \begin{bmatrix} B_t \\ B_{t+1} \\ \cdot \\ \cdot \\ \cdot \\ B_{t+k} \end{bmatrix},$$

$X_{t+i} \geq 0$, for $i = 0, \ldots, k$,

where C_{t+i} = a row vector of expected net returns or expected expenses of a unit of activities in planning period $t + i$, $i = 0, \ldots, k$;[2] this vector is extended over the planning horizon of $k + 1$ periods; X_{t+i} = a column vector containing alternative activities in the planning period $t + i$, $i = 0, \ldots, k$; A_{t+i} = a matrix that contains input-output and transition coefficients for planning periods $t + i$, $i = 0, \ldots, k$; and B_{t+i} = a vector that contains the amounts of resources available for planning period $t + i$, $i = 0, \ldots, k$.

While the structure of this submodel parallels what has been used in previous studies (e.g., Martin and Plaxico), it possesses a distinct feature in the feedback system to provide information on resource availabilities for each successive planning period.[3] The mathematical expression of the feedback system is

$$\text{(2)}\quad B_t = \Lambda_{t-1} B^*_{t-1} + \Gamma_{t-1} B_{t-1}, \quad \text{for } t = 1, 2, \ldots, T,$$

and

$$\text{(3)}\quad B_{t+i} = \Gamma_{t+i-1} B_{t+i-1}, \text{for } i = 1, 2, \ldots, k,$$

where B_t = the column vector of resource amounts estimated to be used in period t for the right-hand-side vector of the MLP submodel; B_{t-1} = a column vector of resource amounts existing at the end of period $t - 1$; B^*_{t-1} = a column vector of resource amounts purchased in the previous period, $t - 1$; Γ_{t-1} = a diagonal matrix containing straight-line depreciation rates for existing inputs, except those purchased in period $t - 1$; the rate of depreciation for nondurable inputs is 1; Λ_{t-1} = a diagonal matrix containing straight-line depreciation rates for inputs purchased in period $t - 1$; and B_{t+1} = a column subvector of resource amounts to be used in successive periods after period t. Equation (3) accounts for resource depreciation that occurs in subsequent periods $t + i$. Depreciation rates in the matrix Γ_{t+i-1} may differ among periods.

Three steps are required to obtain the solution of equations (2) and (3). First, initial resource conditions (i.e., the vector B_0) must be analyzed. Second, the quantity of durable inputs purchased in the preceding period(s) must be determined. Third, depreciation for the durable inputs must be computed. The latter two steps are handled by the simulation submodel.

The Monoperiod Simulation Submodel

The simulation submodel (figure 1) is similar in many ways to models used by Hutton, Hinman and Hutton, and Patrick and Eisgruber. The simulation input data include the current farm plan derived from the MLP submodel, technical and economic data for crops and livestock, prices of inputs, consumption ex-

[2] The subscripts i and k refer to the individual period and the planning horizon, respectively.

[3] Boehlje and White's MLP model readdressed the enterprise choice question each production period. The model of this article performs this same function, i.e., a feedback of new resource levels through the simulator (phase 3).

penditures, inventories of crops and livestock, assets and other financial information, and a stochastic price and yield-generating scheme.

A random number generator (IBM Corporation) is used in conjunction with an exponential smoothing technique (Brown and Meyer, pp. 673–87) to estimate yields and prices of crops and livestock. The procedures are outlined in equations (4) through (7):

$$(4)\qquad S_{j,t}(Y) = \theta Y_{j,t-1} + (1 - \theta)S_{j,t-1}(Y),$$

where $S_{j,t}(Y)$ = the smoothed value for variable Y (yield for crop j or price for product j) in time period t, $Y_{j,t-1}$ = the actual or model-generated yield for crop j or price for product j in time period $t - 1$, and θ = the smoothing constant. $0 \leq \theta \leq 1$.

Initial smoothing values ($S_{j,0}$) and the smoothing constant (θ) were estimated from pre-1967 time-series data (Kentucky Crop and Livestock Reporting Service). The "best" estimate of the smoothing constant ($\hat{\theta}$) is considered to be the one that minimizes the sum of squares of the forecast errors.

In order to correct equation (4) for lag behind any systematic trend in the data, differences between successive smoothed values are used as estimates of trend. Again, exponential smoothing is used on successive differences to compute an average trend. Successive differences are expressed as

$$(5)\qquad C_{j,t}(Y) = S_{j,t}(Y) - S_{j,t-1}(Y),$$

where $C_{j,t}(Y)$ = the change in the smoothed value for variable Y (yield for crop j or price for product j) between periods t and $t - 1$, and $S_{j,t}(Y)$ and $S_{j,t-1}(Y)$ are defined in expression (4).

The smoothed trend ($T_{j,t}(Y)$) is computed by a linear combination of $C_{j,t}(Y)$ and the estimated yield (price) trend ($T_{j,t-1}(Y)$) for time period $t - 1$, i.e.,

$$(6)\qquad T_{j,t}(Y) = (1 - \phi)\, C_{j,t}(Y) + \phi T_{j,t-1}(Y),$$

where ϕ = the trend smoothing constant, $0 \leq \phi \leq 1$.

Finally, the simulated yield or price for a particular product is generated using the following equation and the IBM subroutine for random number generation:

$$(7)\qquad Y_{j,t} = S_{j,t}(Y) + T_{j,t}(Y) + \epsilon_{j,t},$$

where $Y_{j,t}$ = the actual or model-generated yield (or price) in period t, and $\epsilon_{j,t}$ = a stochastic variate affecting the yield or price for product Y, assumed to be distributed $N(0, \sigma^2)$.

After receiving input data the simulator begins executing the decision-operation process for the current farm plan. Recognizing that factors such as lumpiness of durable inputs, uncertainty, and psychological inertia may prohibit the entrepreneur from carrying out the optimal plans as prescribed by the MLP model, the technique of behavioral constraints (Henderson, pp. 242–66) is used through the simulator to take account of such phenomena. Level bounds for enterprises in any given period are specified as

$$(8)\qquad (1 - \beta)\, X_{j,t-1} \leq X_{j,t} \leq (1 + \alpha)\, X_{j,t-1},$$

where $X_{j,t}$ = the level of enterprise j to be produced in period t, $X_{j,t-1}$ = the actual or solution level of enterprise j produced in period $t - 1$, and α and β = maximum allowable percentages of increase and decrease, respectively, from the enterprise level in the previous period(s).

Entering enterprise levels for the current period are determined in the decision-operation process of the simulator by comparing the optimal enterprise levels obtained from MLP with the two bounds.[4] The following decision rules are used: the optimal enterprise level is accepted if it falls within the two bounds, the upper bound is accepted if the optimal level is larger, and the lower bound is accepted if the optimal level is smaller.

Once a modified current farm plan is established, the simulator then implements operations of the plan and executes decisions regarding the additions of production inputs such as land, beef cows, machinery, feeds, etc. Purchase quantities depend on production requirements, resource inventories, and investment decision rules built in the simulator. For example, capital asset purchase or rental decisions are made by the simulator in accordance with two decision rules: (*a*) if during a particular time period the deficiency of a capital input service exceeds its average annual usage by one-third or more, the asset is purchased; otherwise, it is rented;[5] and (*b*) if two or more types of capital assets need to be acquired, the order of purchase depends upon

[4] Upper and lower bounds for each enterprise were estimated from reviews of farm records in the Kentucky Farm Analysis Program, Bluegrass Area, and personal interviews with the farm manager(s). As Sahi and Craddock recently demonstrated, this method is an oversimplification unless the bounds remain relatively unchanged across time. Stability, however, was present for the study applications presented in this article.

[5] This assumes, of course, that sufficient internal funds exist for down-payment or rental costs. If not, the simulator disallows the purchase (rental).

the "degree of necessity" of the items. Necessity rankings assigned to the asset items are subjectively made on the basis of the type of farm business and through personal consultation with the entrepreneur(s). Down-payment percentages are specified on the basis of farm-planning manuals, e.g., Ray and Hudson. Loan requisition and acquisition procedures are processed by the simulator. All debts and repayments are updated and grouped by type of assets and length of the repayment schedule at the end of each period.

Several accounting calculations are included in the simulator—depreciation of capital items, current returns, expenses, income tax payments, a summary of assets, liabilities, and net worth. To estimate family consumption expenditures, a modified version of a consumption function (Trimble, Connor, and Brake) first developed by Brake was adapted for the simulator.

The final portion of the simulator is the report writer (phase 4). It prepares a report for the current period on resource inventories, the farm enterprise organization, a financial summary, and the model-generated prices and yields of the products.

An Empirical Illustration

The model was applied to a tobacco-beef farm located in the Central Bluegrass area of Kentucky, the overriding concern being to illustrate that the model is operational and in concert with the underlying methodological concepts.[6] The application farm's actual enterprise organization and financial positions as of 31 December 1966 and 1970 are shown in table 1. Enterprise alternatives and most of the resource, investment, and borrowing capacity

[6] The application farm was selected by extension specialists prior to model construction or any other phases of this research study. At that time, this farm was believed to be rather typical of central Kentucky beef farms attempting to grow in size. The argument that a representative-type synthesized farm application more thoroughly tests "predictive powers" of a model than a single application farm seems to rest primarily on a single premise, viz., simulated results are in effect compared to an average of actual results rather than one observed set of results. The counter argument—favoring at least initially using a single-case approach—also possesses some degree of validity. First, the farm situation is an actual one. Second, if prior to testing the model the farm is randomly selected from a well-identified population, the single case comparison could have some preferable statistical properties because the variance of an observation (one farm) always exceeds the variance of an average. A representative farm that is constructed from a "good" sample of actual farms obviously would be superior. One that is synthesized from budgets purporting to depict the population may not be.

Table 1. Enterprise Organization and Financial Situation for the Application Farm: 31 Dec. 1966 and 1970 Actual Values

Item	31 Dec. 1966	31 Dec. 1970
Enterprise organization		
Crops[a] (acres)		
Burley tobacco	8.68	8.62
Corn	0	22
Corn silage	10	25
Hay	33	17
Pasture I	249.32	271.38
Pasture II	184	184
Livestock (head)		
Cow calf	71	68
Feeder cattle	62	75
Financial situation		
Assets ($)		
Cash	9,544	2,100
Bonds and other securities	24,500	15,000
Livestock on hand	24,200	43,000
Crops on hand	0	5,000
Machinery[b]	6,900	27,500
Land, buildings	89,000	93,000
Total	154,144	185,600
Liabilities ($)		
Long-term debt	40,000	37,500
Intermediate-term debt	14,000	34,000
Short-term debt	0	10,000
Total	54,000	81,500
Net worth	100,144	104,100

[a] Land acreage totaled 538 in 1966 and 1970. The crop totals shown here do not include land used for three homesteads and some idle land and woodland.
[b] The farm had three full time nonequivalent laborers throughout the initial study periods, 1966–70.

constraints considered in the MLP model are based on the 1966 farm data. (For a more detailed discussion of the MLP formulation for the application farm, see Chien and Bradford.)

Since a review of the farm records reveals a fairly stable enterprise organization during the initial study periods, 1966–70, the same enterprise activities were considered by the MLP submodel during the experimental study periods, 1971–74. This assumption implies that the entrepreneur's preference for existing enterprises remains unchanged, which does not appear unreasonable, given that the planning horizon was assumed to be five years.

Behavioral constraints built into the simulator to reflect the entrepreneur's behavior regarding period-to-period changes in enterprise levels were applied to beef cow-calf and feeder calf enterprises. All cropping enterprises except burley tobacco were either feed grain or forages, for which the activity levels were primarily dependent upon the size of the beef activities. Thus, once the levels of the beef enterprises were determined, the type and quantity of feeds needed to be produced or purchased would be automatically determined by the simulator. Burley tobacco, being restricted by an allotment, did not need behavioral constraints. The estimates of upper and lower bounds were obtained from the application farm's records. Increases in the cow-calf and feeder numbers were restricted to be less than or equal to 10% and 50% per year, respectively. Yearly decreases could be no greater than 10% for the cow-calf enterprise and no greater than 20% for beef feeders.

Growth of the farm firm was measured using three response variables: total assets, net worth, and changes in size of the beef cattle enterprises. Assets and net worth reflect the financial position, while growth in beef numbers is a special feature of this farm. Simulated and actual levels of the response variables are compared for an initial study period, 1966–70, and an experimental study period, 1971–74 (figures 2 and 3). At the time the model was constructed and first tested, actual

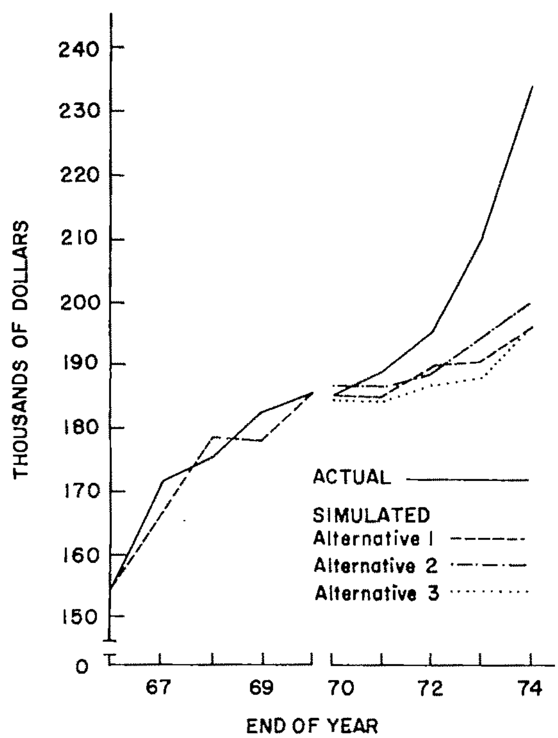

Figure 2. Actual and simulated time paths for firm's total assets

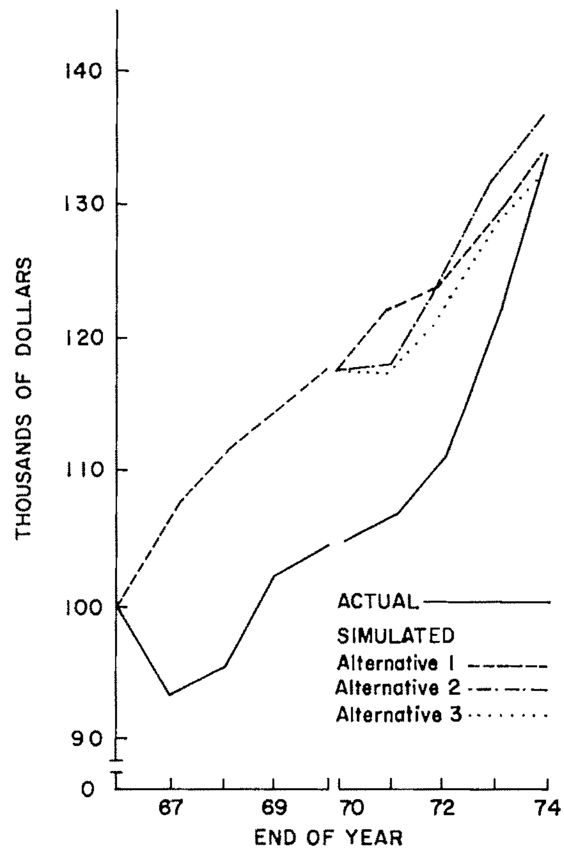

Figure 3. Actual and simulated time paths for firm's net worth

values of response variables were known only for the initial study period, the primary idea being to test the model. Follow-up observations (records) were later obtained for the experimental period for purposes of further testing of initial test conclusions.

Initial Study Period, Testing

For total assets, the simulated response was relatively close to the actual values (figure 2). The simulated time path is neither explosive nor overly damped. Hence, the model possesses at least some of the mechanisms that determine growth in total assets.

The model generated a time path for net worth that after 1967 was consistent with the actual slope but in magnitude was higher than the actual net worth values (figure 3). The departure in magnitude stems from difficulty in accounting for the magnitude of household consumption and from difficulty in incorporating into the model the precise debt payment schedule for the study farm. The farm operator indicated that, because of personal relations with lending agents, he was allowed to retire debts on a very flexible schedule. An examination of farm and household records revealed that over time the operator repaid the loan principal in uneven amounts. Indeed, during the year 1967, the operator actually used some borrowed funds for consumption. Our modified consumption function obviously did not track the behavior for this application firm. Perhaps it is too presumptuous to attempt to a priori track such individual personal behavior especially during any particular year.

Experimental Study Period

Computer-based experiments were conducted with the model to examine the effects of alternative management strategies upon potential growth patterns of the farm firm during 1971–74. Three management strategies (treatments) were compared: continuing fall calving and feeder-cattle operations (a "check treatment"), changing to spring calving and feeder-cattle operations, and adopting a forward pricing or market price hedging strategy with 50% less price variability for feeder calves and feeder cattle.

Experimental results were generated in 1971. Actual values for the response variables (assets or net worth in 1971–74 shown in figures 2 and 3), of course, were not known when these results were generated. Thus, the primary concern should be with comparisons among strategies 1, 2, and 3, not with comparing these strategies to the actual or *ex post* results. The increasing disparity between the actual and projected asset values during the experimental period (1971–74) is largely due to sharp inflationary increases in central Kentucky land values during this period.

Terminal states (end of 1974) of total assets and net worth values were not statistically different among the three strategies. These findings may be partially explained by the fact that spring calving uses pasture as the primary feed, thus reducing the investment in machinery. Consequently, any significant growth in terms of assets or net worth would have to stem from quite a substantial expansion in the beef cow herd, and this is not likely to occur during a period of only four years.

Experimental results also indicated that if the study farm were to continue following fall-calving beef production systems (alternative 1), the size of the breeding herd would have remained constant during the experimental study period (1971–74). However, the number of feeder cattle would have increased from 75 to over 100. This expansion would have stemmed primarily from a reduction in interest expenses and principal payments for the old debts, releasing operating capital for additional feeder cattle.

Substitution of a spring-calving program for the fall-calving operation (alternative 2) would have resulted in expansion of both the beef cow herd size and the feeder cattle enterprise. The number of beef cows in the herd was projected to increase from 71 head at the end of 1970 to 93 head at the end of 1974. The feeder cattle enterprise was projected to expand from 75 to 152 head. This projected expansion can be attributed mainly to the relatively low production costs associated with a spring-calving operation.

The projected enterprise organization under alternative 3 (less price variability) exhibited essentially the same pattern as that of alternative 2. However, projected expansion in the beef cow herd size tended to be more rapid than under alternative 2. Reduction in price uncertainty apparently tends to reduce the complexity of the entire decision-making process, encouraging the operator to expand his farm business whenever markets indicate favorable opportunities.

Summary Remarks

The significance of the farm firm growth modeling described in this article lies in the integration of pertinent economic theories of the dynamic planning behavior of the firm in order to link capabilities of MLP and computer simulation techniques as a means of utilizing their maximum contribution to the prediction of farm firm growth. The integrated multiperiod linear programming, simulation model exhibits descriptive, predictive, stochastic, and dynamic features of the farm firm planning process. This is characterized by the sequential and recursive nature of the model, which contains behavioral constraints, qualitative investment decision rules, and a forecasting technique for stochastic yields and prices.

The empirical illustration indicates that the model is capable of describing and predicting growth patterns of the farm firm. Since the major interest of the economic analyst is to examine average firm growth patterns, the effects of "extreme" values for the stochastic variables may tend to accumulate through the lagged endogenous variables. Such extremes may be averaged out, as Strickland noted, with sufficient replications in the model experiments. Although the model is primarily predictive in nature, experiments allow one to examine the effects of changes in managerial decision processes. Thus, entrepreneurs can identify necessary changes in the firm behavioral mechanisms in order to achieve more nearly optimal behavior consistent with their goals.

Although the use of the model requires a substantial commitment of time and resources for such things as data collection and computer software developments, we believe that the investment is merited because of the importance and complexity of dynamic farm business planning. With an adequate support of software and computer hardware, the proposed modeling technique would be a useful tool to aid the economic analyst in explaining or predicting farm firm growth.

Estimation of Gain Isoquants and a Decision Model Application for Swine Production

Steven T. Sonka, Earl O. Heady, and P. Fred Dahm

Historic estimates of livestock production functions have used repeated observations on the animals to estimate the overall gain surface. The estimates involve autocorrelation accordingly. To circumvent this problem, gain isoquants are estimated directly by means of an instrumental variable approach. Data are from a swine experiment designed for the purpose with 648 hogs. Protein supplement and corn serve as the substitute inputs. Protein supplement is estimated as the instrumental variable. Isoquant equations then are predicted for three weight intervals. Finally, a decision model is applied for economic choice. Comparisons are made for various price sets of recent years.

Key words: autocorrelation, decision model, instrumental variable, isoquants, production function.

A major consideration in any swine-feeding program is the cost of feed required. For a typical Corn Belt swine operation, feed costs are 55% to 60% of the total cost of raising an animal from weaning to market (Burns). Since feed is a major cost to the producer, he needs information relating to the minimum expenditure needed to attain a specified gain, as well as the time required for the gain.

Recently, uncertainty about the most economic ration has increased because of great fluctuations in the cost of major feeds. For example, after the corn blight of the 1970 season, the ratio of the price of a pound of soybean oilmeal to a pound of corn was 1.43 in mid-April 1971 (USDA). But by mid-April 1973, that same ratio had risen to 3.82, more than 2.6 times that of 1971 (USDA). Faced with these wide price gyrations, recommendations for fixed ration proportions, which fail to take into account economic as well as physical relationships, decline in value for the swine producer (Allison).

Because feed costs are a major component of the total cost of producing swine and because the prices of protein supplement and corn have fluctuated widely in the past few years, information on the proper energy-protein mix for various prices of feeds is needed. The primary goal of the study reported in this paper is to estimate substitution ratios between protein supplement and corn and to develop a relatively simple procedure to calculate proper rations for differing protein-supplement, corn-price relationships. A complementary goal of the paper is to determine the value of such information to the producer.

In this article we first describe the experiment conducted to provide the raw input-output or production function data and the techniques employed to overcome the statistical problems inherent in animal-production function analysis. Then the estimated equations and substitutions ratios between corn and protein supplement are reported. In a final section, we describe a simple decision model for minimizing feed costs, which is relevant to many of the nation's swine producers.

Steven T. Sonka is an assistant professor at the University of Illinois, Urbana, Earl O. Heady is the C. F. Curtiss Distinguished Professor of Agriculture, a professor of economics, and the director of the Center for Agricultural and Rural Development and P. Fred Dahm is a research assistant at Iowa State University, Ames.

Journal Paper No. J-8356 of the Iowa Agricultural and Home Economics Experiment Station, Ames, Iowa, Project No. 2013. Data for this analysis were supplied by Moorman Manufacturing Company. The authors wish to acknowledge W. A. Fuller of Iowa State University and H. D. Hutchinson and R. F. Klay of Moorman Manufacturing Company for the substantial contributions to the project described herein and two anonymous reviewers for their helpful comments.

The Basic Experiment

To determine substitution ratios between protein supplement and corn for growing swine, gain and feed consumption data for 648 animals were analyzed. All of the animals were a three-way cross of Hampshire, Yorkshire, and Duroc breeds and were raised in confinement facilities in pens of six animals. The experiment was designed specifically to allow estimation of gain (production) functions and marginal rates of feed substitution.

The 648 hogs were grouped in five separate experiments with animals within an experiment allotted to replications on the basis of weight, sex, and litter. For three of the experiments (408 animals), the starting weight averaged 60 pounds per head. These animals were fed a growing ration until they reached 100 pounds per animal and then were switched to a finishing ration for the remainder of the experiment. The growing rations incorporated a 45% protein supplement and six protein levels (13%, 14%, 15%, 16%, 17%, and 18%) were used in the rations. The finishing rations incorporated a 41% protein supplement and were fed over two weight intervals or periods, from 100 to 150 pounds and from 150 to 215 pounds. For the first of these two intervals, seven protein levels (10%, 11%, 12%, 13%, 14%, 15%, and 16%) were used; for the second interval, six protein levels (10%, 11%, 12%, 13%, 14%, and 15%) were used.

For the remaining two experiments, containing 240 animals, the starting weight averaged 100 pounds per head and only the finishing ration was fed for the 100 to 150 and the 150 to 215 pound intervals. Therefore, the estimates for the growing weight interval (60 to 100 pounds) are based on 408 animals and the estimates for the finishing weight intervals (100 to 150 pounds and 150 to 215 pounds) are based on data from 648 animals.

Estimation of the Production Relationship

Estimation of meat animal production relationships typically presents the researcher with at least two major econometric problems. The first arises because, normally, successive observations must be taken from the same experimental unit (in this case, a lot of six hogs) as the animals proceed over a gain path (Heady et al.). Because the same experimental unit is used for repeated observations, one assumption used in the ordinary least squares procedure, that of zero covariance for the disturbance terms, can be violated (Johnston).

Although assumptions can be made as to the autoregressive nature of the disturbance terms (Heady et al., Paris et al.), a radically different approach was adopted for this analysis. Normally, a production function is estimated from a series of observations on weight and feed intake and then isoquants for corn and protein supplement are derived (Dillon, Heady and Dillon). For this analysis, however, the total quantity of corn and protein supplement needed by each lot to complete each of the three weight intervals (60 to 100 pounds, 100 to 150 pounds, and 150 to 215 pounds) was calculated. From this, we know the feed necessary to attain a specified amount of weight gain (40 pounds, 50 pounds, and 65 pounds per hog, respectively). Now, instead of estimating the traditional production function, it is possible to directly estimate a gain isoquant over each of the three weight intervals.[1] These isoquants take the form

$$C_i = f_i(PS_i), \tag{1}$$

where PS_i = pounds of protein supplement consumed over the ith weight interval and C_i = pounds of corn consumed during the ith weight interval.

Although this procedure does not supply as much information as does estimation of the total production function in the conventional manner, it does provide direct estimates of the trade-offs (marginal substitution rates) between corn and protein supplement in growing swine. Furthermore, because each experimental unit is used only once in each weight interval, the serial correlation problem caused by using successive observations to estimate a production or gain surface is eliminated.

The second estimation problem arising in animal production studies stems from the basic nature of animal production. This problem arises because the animal, not the experimenter or the farmer, controls the rate at which feed is consumed (Askalani, Johnston). The researcher can dictate how much the ani-

[1] Conventional production functions from the experimental data have been estimated. Isoquants derived from them can be compared with those estimated directly as in this paper. While results are quite similar, the approach presented in this paper seems preferred.

mals eats in a feeding period but not the days needed to consume a set quantity of feed, or the researcher can specify the days in the trial but not the total feed consumed. Because the swine used in this analysis were fed *ad libitum* (i.e., full fed), it would not be proper to consider either the quantity of protein supplement consumed (PS_i) or the quantity of corn consumed (C_i) as fixed variables.

To overcome the serious estimation problem posed by measurement error in the independent variable, an instrumental variable estimator is employed in the analysis (Duloy). This procedure requires an instrumental variable uncorrelated with the equation disturbance term and the measurement errors (Johnston).

As previously noted, when full fed the animal determines the rate of feed consumption in an experiment. The experimenter or the farmer can only control the proportion of the ration that is protein. Therefore, the percentage of protein is the variable of interest for the swine producer. The instrumental variable used in this analysis is then the predicted quantity of protein supplement based on an equation with percentage of protein and percentage of protein squared as independent variables. Among the several evaluated, this algebraic form conformed statistically to the data better than others.

This two-step estimation procedure first requires estimation of the instrumental variable (predicted protein supplement). This equation is

$$PS_i = g(R_i), \tag{2}$$

where R_i = the percentage of protein in the ration in weight period i and PS_i is defined as before. An equation in the form of equation (2) is estimated for each weight interval and used to determine a predicted quantity of protein supplement consumption for each experimental unit. This predicted protein supplement quantity is then used to determine that isoquant equation as given in

$$C_i = h(PS^*_i), \tag{3}$$

where PS^*_i = the predicted quantity of protein supplement from equation (2) for the ith weight period and C_i is defined as before. Because the actual isoquant equation utilizes predicted protein supplement, ordinary least squares applied to this equation gives the instrumental variable estimates.

For each weight interval, one equation is needed to predict the quantity of protein supplement consumption and another equation must be estimated to determine the relationship between protein supplement and corn. Because the percentage of protein in the ration also affects the rate of gain an animal can attain, a third equation is estimated that relates the number of days needed to attain the specified gain to the percentage of protein in the ration as in

$$D_i = k(R_i)\ , \tag{4}$$

where D_i = the number of days required to complete the ith weight interval and R_i is defined as before.

Estimation Results

Instrumental Variable Equations

For each weight interval, the equations estimating the relationships between protein supplement consumption and the percentage of protein in the ration are[2]

(5) Interval I (60 to 100 pounds):

$$\ln PS_1 = -\underset{(2.12)}{1.6931} + \underset{(4.68)}{0.4832}\ R_1 - \underset{(3.57)}{0.0118}\ R_1^2,$$
$$R^2 = 0.899 \qquad F = 288.88;$$

(6) Interval II (100 to 150 pounds):

$$\ln PS_2 = -\underset{(7.95)}{3.4830} + \underset{(11.54)}{0.7962}\ R_2 - \underset{(8.45)}{0.0225}\ R_2^2,$$
$$R^2 = 0.956 \qquad F = 1{,}110.42;$$

and

(7) Interval III (150 to 215 pounds):

$$\ln PS_3 = -\underset{(10.25)}{5.1616} + \underset{(13.55)}{1.1035}\ R_3 - \underset{(10.57)}{0.0344}\ R_3^2,$$
$$R^2 = 0.962 \qquad F = 1{,}317.03;$$

where PS_i and R_i are defined as before. The conventional R^2 and F-statistics also are included for each estimated equation. (The figures in parentheses are t-values for the estimated statistics.)

Isoquant Equations

Equations (5), (6), and (7) are used to determine predicted protein supplement consumption data for each weight interval. These predicted values are then used as independent variables in the following isoquant equations:

[2] The figures enclosed in parentheses are t-values for each coefficient.

(8) Interval I (60 to 100 pounds):

$$\ln C_1 = \underset{(32.99)}{6.1630} - \underset{(9.33)}{0.5898} \ln PS^*_1,$$
$$R^2 = 0.740 \qquad F = 188.13;$$

(9) Interval II (100 to 150 pounds):

$$\ln C_2 = \underset{(63.26)}{6.2292} - \underset{(13.14)}{0.4405} \ln PS^*_2,$$
$$R^2 = 0.691 \qquad F = 232.39;$$

and

(10) Interval III (150 to 215 pounds):

$$\ln C_3 = \underset{(81.61)}{6.4378} - \underset{(14.16)}{0.3526} \ln PS^*_3,$$
$$R^2 = 0.769 \qquad F = 346.43;$$

where C_i and PS^*_i are defined as before.

Equations (8), (9), and (10) describe the substitution of corn and protein supplement for each weight interval and are graphed in figures 1, 2, and 3, respectively. Each of these contours indicates the predicted combinations of corn and protein supplement that can be used to attain the gains specified for each weight interval.

The slope of an isoquant at any particular point is of course the marginal rate of substitution of protein supplement for corn (and vice versa). Marginal rates of substitution for the three interval isoquants at various protein supplement levels are given in table 1.

Within each weight interval, the data of table 1 indicate that the rate of replacement of corn by protein supplement declines as more protein supplement is included in the ration. In interval I, for example, 1 pound of protein supplement replaces 5.39 pounds of corn at 12 pounds of protein supplement but only 2.39 pounds at 20 pounds of protein supplement. Similar diminishing marginal substitution rates prevail over other weight intervals. The data of table 1 also indicate that the replacement of corn by protein supplement declines as an animal shifts from the growth stage of development to the fattening stage. For example, at 24 pounds of protein supplement in interval I, 1 pound of protein supplement replaces 1.79 pounds of corn; at the equivalent protein supplement level in interval II, 1 pound of protein supplement only replaces 1.67 pounds of corn; and at the equivalent protein supplement level of interval III, 1 pound of protein supplement replaces 1.55 pounds of corn.

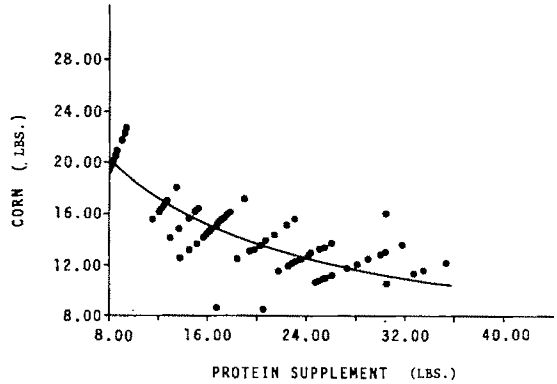

Figure 2. Interval II isoquant (● = original observation)

Time of Gain Equations

The classical textbook isoquant supposes that time is constant as the specified level of production is attained by any one of a range of input ratios x_i/x_j, where x_i and x_j are the inputs being substituted for each other. However, while the mix of inputs may not change the time period for the isoquant in certain industrial processes, it does for inputs such as corn

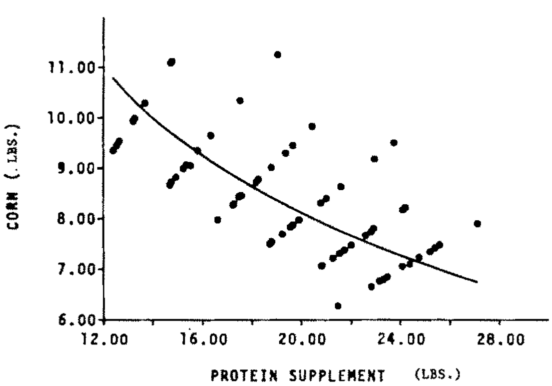

Figure 1. Interval I isoquant (● = original observation)

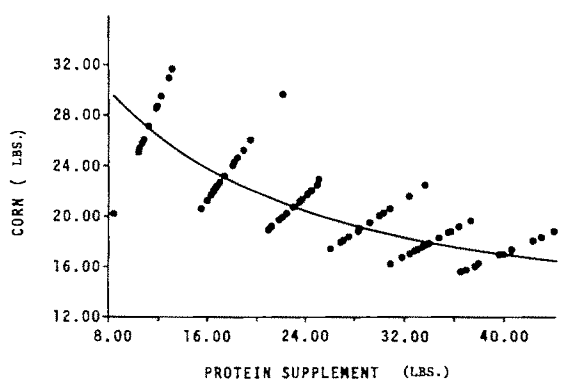

Figure 3. Interval III isoquant (● = original observation)

Table 1. Marginal Rates of Substitution of Protein Supplement for Corn

Pounds of Protein Supplement in Period I*	Interval I		Interval II		Interval III	
	Percentage of Protein	Substitution Rates	Percentage of Protein	Substitution Rates	Percentage of Protein	Substitution Rates
12.0	12.5	5.39	11.8	4.52	11.5	3.96
16.0	14.2	3.41	13.0	2.99	12.7	2.69
20.0	16.0	2.39	14.3	2.16	13.8	1.99
24.0	17.9	1.79	15.6	1.67	14.9	1.55
28.0	20.0	1.40	16.8	1.33	15.9	1.26

* Because the three weight intervals are defined for different quantities of gain, the protein supplement levels of period I were converted into pounds of protein supplement per pound of gain, and this ratio was used to determine equivalent protein supplement quantities for intervals II and III. The equivalent levels are 15, 20, 25, 30, and 35 pounds in interval II and 19.5, 26.0, 32.5, 39.0, and 45.5 pounds in interval III.

and protein supplement used in a biological production process such as swine. This problem has been discussed elsewhere (Heady and Dillon, pp. 291–99) and a pork costulator was devised (p. 301) to allow the producer to select between the least-cost ration and the least-time ration, if the latter allowed marketing hogs during a period of higher prices. We treat time of gain in a somewhat different manner here.

Although feed constitutes the major portion of the total production costs for swine, labor and capital costs also are important. Both latter cost components are affected by the number of animals the farmer can feed in a year and therefore by the time required to feed out a group of hogs. Also, because the price received for hogs varies, the farmer may decide to feed a higher cost ration if a faster rate of gain allows him to receive a higher price for his product. Because of these time-influenced considerations, the relationship between the time required to gain a specified weight and composition of the ration were estimated and are presented:

(11) Interval I (60 to 100 pounds):

$$D_1 = \underset{(6.04)}{122.0728} - \underset{(4.29)}{11.2051}\, R_1 + \underset{(3.82)}{0.3191}\, R_1^2,$$
$$R^2 = 0.646 \qquad F = 59.42;$$

(12) Interval II (100 to 150 pounds):

$$D_2 = \underset{(10.47)}{259.1969} - \underset{(8.51)}{33.0176}\, R_2 + \underset{(7.77)}{1.1709}\, R_2^2,$$
$$R^2 = 0.643 \qquad F = 92.83;$$

and

(13) Interval III (150 to 215 pounds):

$$D_3 = \underset{(8.04)}{270.9710} - \underset{(6.30)}{34.3196}\, R_3 + \underset{(5.69)}{1.2368}\, R_3^2,$$
$$R^2 = 0.579 \qquad F = 70.91;$$

where D_i and R_i are defined as before.

These equations indicate that as the percentage of protein in the ration increases, the number of days needed to attain the specified gain declines but at a diminishing rate. This relationship is further illustrated in figures 4, 5, and 6, which graph actual and predicted data for equations (11), (12), and (13).

Economic Implications

The equations and relationships presented in the previous section describe the physical process of the growing animal. These data provide only part of the information needed by the pork producer in determining the economically-optimum ration. He requires a decision criteria that will allow him to select the minimum-cost ration given his constraints. In this section, therefore, a simple decision process for selecting a least-cost ration is described. This process is adequate for a large portion of the nation's pork producers.

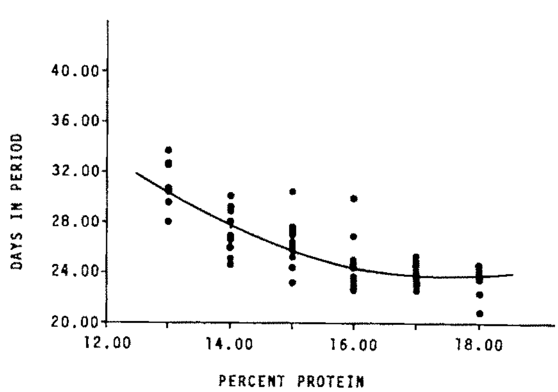

Figure 4. Days in period I (● = original observation)

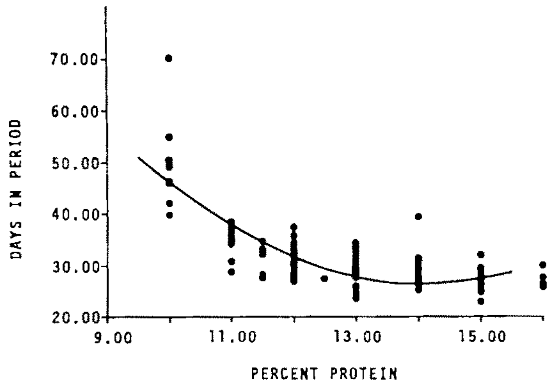

Figure 5. Days in period II (● = original observation)

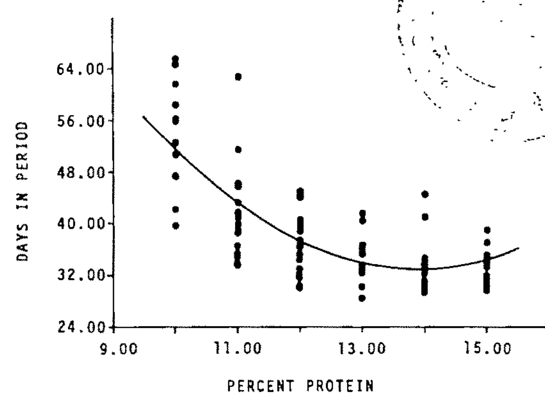

Figure 6. Days in period III (● = original observation)

The Decision Model

The decision rule adopted for this analysis is based on maximization of profit in an unconstrained optimization framework. In this formulation, maximum profit is attained when corn and protein supplement are mixed in a ratio that allows the marginal rate of substitution of protein for corn to just equal the protein-supplement, corn-price ratio. This equality can then be rearranged to solve for an optimum quantity of protein supplement as in

$$(14) \qquad \overline{PS}_i = [(P_{ps}{}^i/P_c)/a_i]^{b_i},$$

where $\overline{PS}_i$ = the optimum quantity of protein supplement in weight interval i, $P_{ps}{}^i$ = the price of protein supplement in the ith interval, P_c = the price of corn, and a_i and b_i = constants for interval i (derived from the marginal rate of substitution equations).[3]

For each weight interval, the optimal quantity of protein supplement ($\overline{PS}$) determined in equation (14) can then be inserted into the proper isoquant equation for each interval, equation (8), (9), or (10), and an optimal quantity of corn can then be calculated. But, as mentioned earlier, the farmer does not control the quantity of feed consumed in an *ad libitum* feeding system. He can only control the percentage of protein in the ration. It is easy to calculate the optimum percentage, however, given the data available. This calculation is

$$(15) \quad \overline{R}_i = (\overline{PS}_i PPS_i + \overline{C}_i PC)/(\overline{PS}_i + \overline{C}_i),$$

where $\overline{R}_i$ = the optimum percentage of protein for interval i, $\overline{C}_i$ = the optimum quantity of corn for interval i, PPS_i = the percentage of protein in the protein supplement fed in period i (either 45% or 41%), PC = the percentage of protein in corn, and $\overline{PS}_i$ is defined as before.

The decision process just described would insure least-cost pork production if the farmer had no alternative uses for the fixed resources allocated to swine production. This would be relevant for the producer who farrows only once a year and whose swine equipment and buildings lie idle after his one batch of hogs is fed. But because many producers do not conform to this situation, the decision process was extended to take into account the time required for the production process. For each weight interval, the optimal percentage of protein ($\overline{R}_i$) can be inserted into the proper time of gain equation, equation (11), (12), or (13), and the total number of days needed to complete the production process determined.

If the hog feeder either farrows or purchases his replacement animals at specified times, he can then determine if the optimum feed mix (with no time constraint) will result in completion of the production process sufficiently soon to free his facilities for the next group of feeder animals. If not, he can adjust the percentage of protein in the ration until his time constraint is satisfied.[4] A numerical example

---

[3] Statistical analysis of the experimental data indicated that ration carry-over effects from one interval to the next were not significant. This result would seem to be plausible only when a narrow range of rations is considered, as in this example, and when none of the rations evaluated are severely nutritionally deficient.

[4] The only type of producer for which this process is not sufficient is one who can acquire replacement animals immediately after marketing each group of animals. The criteria for this producer would be to maximize profit per day (Dillon) as given in

$$(17) \qquad \pi/D = P_y Y - S - \sum_{i=1}^{3} (P_c C_i + P_{ps}{}^i PS_i)/\sum_{i=1}^{3} D_i,$$

where π/D = profit per day, S = the fixed setup cost per time period, P_y = the expected price of swine at finishing, D_i = the number of days needed to complete the ith interval with the optimum ration, Y = the finished weight of the animal (215 pounds), and P_c, C_i, $P_{ps}{}^i$, and PS_i are defined before.

Table 2. Least-Cost Rations for Actual Protein-Supplement, Corn-Price Ratios of the Last Five Years

	Interval I			Interval II			Interval III		
	Price Ratio[a]	Percentage of Protein	Days Required	Price Ratio[a]	Percentage of Protein	Days Required	Price Ratio[a]	Percentage of Protein	Days Required
Apr. 1975[b]	1.34	18.0	23.8	1.23	16.0	30.6	1.23	15.0	34.4
Nov. 1974[b]	1.18	18.0	23.8	1.08	16.0	30.6	1.08	15.0	34.4
Apr. 1974[b]	1.34	18.0	23.8	1.24	16.0	30.6	1.24	15.0	34.4
Nov. 1973	1.93	17.3	23.7	1.77	15.2	27.9	1.77	14.2	33.0
Apr. 1973	3.62	13.9	27.9	3.33	12.6	29.2	3.33	12.0	37.5
Nov. 1972	2.86	15.2	25.5	2.63	13.4	27.0	2.63	12.7	34.6
Apr. 1972	2.33	16.2	24.3	2.15	14.3	26.5	2.15	13.4	33.1
Nov. 1971	2.17	16.6	24.0	2.00	14.6	26.8	2.00	13.7	32.9
Apr. 1971[b]	0.95	18.0	23.8	0.88	16.0	30.6	0.88	15.0	34.4
Nov. 1970[b]	1.12	18.0	23.8	1.03	16.0	30.6	1.03	15.0	34.4

[a] Each price ratio compares the price of a pound of protein supplement to the price of a pound of corn. The protein supplement used in this example is a mixture of 44% soybean oilmeal, meat and bone meal, salt, and minerals. The prices used are midmonth prices for the specified dates on a Chicago basis (USDA).
[b] Whenever the protein percentage recommended by the decision process exceeds the protein levels actually used in the basic experiment it is assumed that the maximum percentage actually used (18% in interval I, 16% in interval II, and 15% in interval III) would be recommended and the days would correspond to that protein level.

of the decision process is given in the following section.

Empirical Examples

To illustrate the effect feed price fluctuations might have on formulation of a least-cost ration, percentage protein recommendations have been generated using mid-April and mid-November prices of the last five years. Table 2 presents these protein percentages as well as the actual protein-supplement, corn-price ratios and the estimated number of days needed to complete each interval.

The data of table 2 indicate the extent to which feed prices have varied in the last five years. After the corn blight of 1970, the protein-supplement, corn-price ratio fell, reaching 0.95 for interval I and 0.88 in intervals II and III in April 1971. But as the world demand for soybean oilmeal expanded (in part due to a poor anchovy harvest), the price of protein supplement increased at a much faster rate than did the price of corn. By April 1973, the protein-supplement, corn-price ratio had reached 3.62 for interval I and 3.33 for intervals II and III. But after that point, the price ratio of protein supplement to corn receded, being 1.34 for interval I and 1.23 for intervals II and III in April 1975.

Reacting to these wide price fluctuations, the protein percentage recommended by this decision process varies considerably. For each of the weight intervals, the lowest protein recommendations, 13.9%, 12.6%, and 12.0%, would have occurred in April 1973. But with relatively cheaper protein supplement, the optimal protein percentage increases, both before and after that date.

During both the early and the later periods of the last five years, the price of corn was high relative to the price of protein supplement. For five dates (November 1970, April 1971, April 1974, November 1974, and April 1975), the recommended percentage exceeds the highest percentage considered in the analysis. For those five periods, therefore, a recommendation equal to that highest protein percentage in the experiment (18% in interval I, 16% in interval II, and 15% in interval III) would be provided to the swine producer.

Each of these protein recommendations implies a different length of time to complete the growth process. These time requirements are also detailed in table 2 and would give the pork producer an indication of the time period for which his facilities would be utilized by one group of animals.[5] For example, feeding the ration recommended for April 1973 requires ninety-five days to complete the growing process. If this period was too long to allow mar-

[5] Since rate of growth is greatly affected by such things as genetic characteristics, weather stress, and breed, in addition to ration composition, it may be more useful to the individual producer to present the time requirements in terms of deviation from the average length of time required. Then, using an average finishing period relevant for his own system and animals, he could consider the effect of different rations on utilization of his facilities.

keting at a specific price peak or to free facilities for another farrowing, the producer could introduce more protein into the ration to shorten the feeding time.

As further illustration of an application of the isoquant equations derived previously, the rations of table 2 can be compared with a recommended ration that does not take into account fluctuations in feed prices. To determine such a standard ration, equations (11), (12), and (13) can be used to indicate the ration that will achieve maximum rate of gain by solving equation (15) for R_i:

$$\frac{\alpha D_i}{\alpha R_i} = 0. \tag{16}$$

Applying this formulation to each of equations (11), (12), and (13) results in estimates of protein percentages for maximum daily rate of gain of 17.56% for interval I, 14.10% for interval II, and 13.87% for interval III. The second derivative for each equation is positive; thus, conditions for minimization are met. Converting these percentages to whole numbers, as would be practically useful, and inserting the rounded values into the proper time of gain equation results in an eighty-three-day minimum requirement for completion of the growing and finishing periods.

Cost of feed required using the least-cost rations can be compared with the cost of feed using the standard ration. (The protein recommendations of the standard ration, 18%, 14%, and 14%, are also consistent with general swine-feeding recommendations (National Academy of Sciences). For each of the ten dates identified in table 2, feed cost and time requirements of the least-cost recommendations are compared with those of the standard ration in table 3.

A number of interesting factors are identified by the data of table 3. One of the most striking of these items is the almost doubling of feed costs from the first part of the 1970s to the latter part of the five-year period. This sudden surge in input costs illustrates the pressure placed on livestock producers in recent years.

The comparison data for feed costs show that the cost savings per head from using a least-cost ration are rather small. Of course, when applied to all the animals a producer has on feed over a number of years the savings grow to be more substantial. Also when both corn and protein prices are at higher levels, as in the last few periods, the potential for savings increases. When protein prices are high relative to the price of corn (as in April 1973), the cost advantage of using a lesser quantity of protein improves.

The data of table 3 also indicate that the number of additional days required by using the least-cost ration are generally quite small. This slight increment in time on feed indicates that the least-cost recommendations could be useful to many of the nation's hog producers who have some slack time between groups of animals on feed. Except for the April 1973 example, the additional days required comprise less than a week; and in the April 1973

Table 3. Comparison of Feed Costs and Time Requirements for Least-Cost Rations with Those of a Standard Ration

	Least-Cost Ration						
	Percentage of Protein						
	Interval I	Interval II	Interval III	Feed Cost[a]	Days Required	Feed Cost Compared to Standard Ration[b]	Days Required Compared to Standard Ration[b]
Apr. 1975	18	16	15	24.30	89	−0.30	6
Nov. 1974	18	16	15	29.43	89	−0.47	6
Apr. 1974	18	16	15	22.48	89	−0.28	6
Nov. 1973	17	15	14	23.49	84	−0.05	1
Apr. 1973	14	13	12	18.32	93	−0.68	10
Nov. 1972	15	13	13	13.88	87	−0.17	4
Apr. 1972	16	14	13	12.54	85	−0.04	2
Nov. 1971	17	15	14	10.15	84	−0.01	1
Apr. 1971	18	16	15	13.42	89	−0.13	6
Nov. 1970	18	16	15	12.59	89	−0.05	6

[a] Over the three intervals.
[b] The standard ration as defined here recommends 18% protein in interval I, 14% protein in interval II, and 14% protein in interval III. This ration results in maximum rate of gain and 83 days would be required with this ration.

case, the potential for savings in feed costs was the highest of the periods analyzed.

The small savings in feed costs per head indicated in table 3 underscores the need for decision procedures that provide information at low cost. Decision procedures that involve relatively high acquisition and utilization costs may not be attractive to producers when the savings to be gained are small.

Summary

The analysis discussed in this paper determined substitution ratios between protein supplement and corn for growing and finishing swine and illustrated how these ratios could be used to calculate least-cost rations for swine. The estimation process adopted here involved direct determination of gain isoquants to overcome the autocorrelation problems usually inherent in livestock production analysis. Because the independent variable, protein consumption, was a random variable correlated with the disturbance term of the isoquant equation, an instrumental variable procedure was also utilized.

The substitution ratios resulting from the estimation procedure were generally consistent with expected nutritional constraints. One pound of protein supplement could substitute for a lesser quantity of corn as the percentage of the ration that was protein supplement increased. Also, 1 pound of protein supplement replaced a larger quantity of corn for smaller animals than for larger.

The decision process illustrated in this article was based on the decision rule of maximization of profit. Time was not directly introduced into the decision process although estimates of the time required to reach market weight were presented. The resulting rations may not be proper, therefore, for farmers who run a continuous feeding system and have replacement animals available immediately after facilities become empty. The decision process presented here, however, is relevant for that segment of the swine industry that does not have replacement animals available instantaneously. The empirical examples calculated for this article show that the large feed price swings of the recent past should result in ration changes to achieve least-cost production. The decision process presented here also has the advantage of being simple enough to be used by farmers either by using a mechanical device similar to the "Pork Costulator" (Heady and Dillon) or tables of price ratios and protein percentages. The estimates of feed cost savings generated in the paper underscore the need for a relatively simple and inexpensive decision aid if it is to be useful to producers.

Recent Changes in Beef Grades: Issues and Analysis of the Yield Grade Requirement

Wayne D. Purcell and Kenneth E. Nelson

The recent change in beef grades has stimulated discussion and opposition. Changes designed to improve the efficiency of the beef-marketing system are being opposed by groups who adopt a micro perspective. The move to required yield grading continues to draw opposition. Analysis of original data from 118 beef carcasses and data from published studies indicates trimming procedures on fabricated cuts are important determinants of the change in cutability across yield grades. Research designed to investigate the implications of different trimming procedures is needed to clarify the applicability of yield grades.

Key words: applicability, cutability, trimming procedures, value differences, yield grades.

Grades and grading are an integral part of the beef-marketing system. Much has been written on such subjects as the economic function of grades, what constitutes an effective set of grading standards, and the role that grades have played in the changing structure of the beef industry. Particular attention has always been paid to proposed revisions in either grade standards or grading procedures. In the 1960s there were two important sets of proposed changes. First came the dual grading system proposal of 1962 and then the change in marbling requirements and the introduction of separate yield grades in 1965.

The period 1965–73 was free of major change. On 10 September 1974, a series of significant changes in beef grade standards was proposed by the U.S. Department of Agriculture. They were elimination of conformation as a factor in determining quality grade, initiation of a "flat-line" marbling requirement for the Prime, Choice, Good, and Standard grades that eliminated the requirement for increased marbling during A maturity (nine to thirty months of age), and initiation of required yield grading for all carcasses that are quality graded.

A ninety-day period for comments followed the September 10 announcement. The comments were evaluated, and in early March 1975 the USDA announced the new standards and procedures would go into effect on April 15. On April 11, however, a coalition of independent packers and consumer advocate groups secured a court injunction and blocked enactment of the proposed changes. The injunction was set aside in response to a USDA appeal in November 1975. On 13 January 1976, the USDA announced the new standards would go into effect on February 23. Efforts to secure a second court injunction were denied and the new procedures were instigated. In early March, however, court actions were continuing in an attempt to have all or part of the new procedures discontinued.

The purpose of this paper is two-fold. First, attention is drawn to the reasons for the opposition to the changes in beef grades. Second, the informational base underlying the move to required yield grading is examined. The results of a detailed cutability analysis of 118 beef carcasses are reported as a contribution to the literature that establishes the quantitative relationship between yield grades and changes in carcass cutability.[1]

Wayne D. Purcell is a professor in the Department of Agricultural Economics at Oklahoma State University, Stillwater, and Kenneth E. Nelson is an agricultural economist with Economic Research Service, U.S. Department of Agriculture, Urbana, Illinois.

Journal Article No. 3007 of the Oklahoma Agriculture Experiment Station.

---

[1] Cutability is used to describe the percentage estimated by the following ratio: (weight of lean, retail cuts from a beef carcass)/(cold carcass weight).

The Competing Factions and a Changing Environment

Reaction to the proposed changes was and is affected by the internal dimensions of the beef marketing system. The USDA promotes change that would facilitate attainment of traditional objectives such as increases in pricing efficiency, more accurate identification of product value, and increases in overall production efficiency. Realization of these objectives could improve efficiency of the beef-marketing system as a whole. But decision makers at any one stage in the system operate from a somewhat different perspective. The manager of an individual firm tends to focus on short-run implications of change and to worry first about firm interests and not the needs of the system as a whole. Changes in grades and grading procedures are likely to be opposed if the changes appear to threaten the competitive position of the firm or require change in procedure internal to the firm.

Such opposition to change in the grading standards is not new. The dual grading proposal of 1962 eliminated conformation as a variable in determining quality grade and introduced a "dual" grade to measure carcass cutability (Grange 1972). Producer groups objected to the elimination of conformation, and a compromise position was adopted by the USDA in its 1965 announcement (Grange 1975). Conformation was reinstated as a factor in determining quality grade. Yield grades, measuring cutability differences, were introduced as separate grades.

A new faction became active in opposition to the 10 September 1974 proposal. Consumer advocate groups opposed the proposed changes in marbling requirements. They contended that the "flat-line" approach to marbling requirements would mean a significant reduction in quality of product with no assurance of a concurrent reduction in price; that is, consumers would be forced to pay Choice prices for Good grade beef. Working with a group of independent packers who opposed required yield grading, the consumer groups helped secure the original court injunction.

A significant body of literature largely invalidates the contentions of the consumer groups with regard to the suggested decrease in quality. Available research results that test the relationship between marbling and overall eating quality reveal a positive but very small correlation (Dunsing, Jeremiah et al., Parrish et al.). In the *Federal Register,* the Agricultural Marketing Service, USDA, having reviewed the literature, concluded ". . . that in beef from cattle up to about 30 months of age (A maturity) changes in maturity have no significant effect on beef palatability" (Peterson, p. 11,536).

Several producer groups took the other side and applauded the proposed changes. Among the potential benefits mentioned were decreased slaughter weights due to the flat-line marbling requirement, improved grain conversion rates given anticipated 15 to 30 pound reductions in fed cattle slaughter weights that eliminate gain at the end of the feeding period when conversion rates (and the marginal cost of production) are relatively high, and increased pricing efficiency as a result of the required yield grading that identifies value differences due to variations in cutability within the Choice or other quality grade and brings these value differences into the pricing process. Earlier economic analyses have supported the positive position taken by these producer groups (Nelson and Van Arsdall, Purcell).

The provision calling for required yield grading continues to draw adamant opposition from beef packers. Most observers, including USDA officials, agree this is the part of the proposed changes that is most important from an economic viewpoint and the change most likely to precipitate long-run adjustments.

The message to be gleaned from the events of the period from 10 September 1974 through early 1976 is clear: change in the beef-grading standards, even change that has solid theoretical support, is likely to be opposed unless all groups that feel they will be affected are convinced of the merits of the proposed change. Attention therefore shifts to the adequacy of the informational base that supports the changes. The remainder of this analysis examines the informational base underlying the move to required yield grading.

The Change to Required Yield Grading

The theoretical and empirical support for the use of a mechanism to measure differences in carcass cutability is impressive. Differences in cutability within the Choice (or other) quality grade are well documented (Dinkel et al.; Epley et al.; Henrickson and Monroe; Stringer et al.). Such differences in cutability

Table 1. Distribution of Carcasses Used in Developing the Murphey Equation by Grade and Class

Grade	Class			Total by Grade
	Steers	Heifers	Cows	
		(No. of Head)		(No. of Head)
Prime	19	4	—	23
Choice	19	23	—	42
Good	23	13	—	36
Standard	14	4	—	18
Commercial	—	—	20	20
Utility	8	—	11	19
Cutter	—	—	2	2
Canner	—	—	2	2

Source: Murphey et al.

cause significant variation in carcass value. The adoption and use of a mechanism such as yield grading seems imperative if these value differences are to be brought into price negotiations and provide for price premiums or discounts.

Yield grading appears to be consistent with the commonly stated theoretical goals of grading. Breimyer notes that one of the objectives of grading is to provide a vehicle for sending signals up and down the production-distribution lines (p. 6). The principal objective of an ideal standard should be to aid the consumer in telling the producer what she or he considers desirable by setting up a chain of information between consumer and producer (Kohls, p. 287). Marketing economists discuss the issue under the label of "pricing efficiency." For yield grades to significantly improve the level of pricing efficiency, it would appear that at least two requirements must be met. First, yield grades must be broadly used. It is difficult to generate consistent and identifiable price signals when part of the carcasses are yield graded and the remaining carcasses are priced using other criteria of value. But a second requirement, one that must be met before widespread adoption could be expected, is that of applicability under industry operating conditions.

Development of Yield Grades

Examination of the literature reveals the base for the USDA's yield grade standards was developed in a paper by Murphey and associates in 1960. The distribution of the carcass data used in estimating the parameters of the Murphey equation is presented in table 1 by classes and grades.

When the yield grades were officially introduced in 1965, five yield grades were identified. According to the standards, a beef carcass typical of a yield grade will cut out 2.3% more lean, semiboneless retail cuts from the round, loin, rib, and chuck than a carcass of the next lower (higher number) yield grade (Murphey et al.). For the entire carcass, however, the reported difference in lean retail cuts is 4.6% of carcass weight per yield grade (USDA 1968). Estimates of percentage differences in yield of lean cuts for the total carcass are published monthly in the USDA's *Livestock, Meat and Wool Market News* with accompanying estimates of value differences between yield grades.

Research on Cutability

The research reported in this paper, hereafter referred to as the Purcell-Nelson study, details cutout tests conducted on 118 beef carcasses in a commercial breaking plant. A total of 83 of the 118 carcasses were graded Choice or better (four graded Prime) and the remaining thirty-five were graded Good. The distribution of the 118 carcasses by yield grade groupings is shown in table 2.

All carcasses were broken to the same set of boneless retail cuts, a set of cuts contained in the USDA's Institutional Meat Purchase (IMP) Series 100 specifications (USDA 1970).

Table 2. Distribution of the 118 Steer Carcasses Analyzed by Yield Grade Groupings

Yield Grade Grouping	No. of Carcasses
1.0–1.9	3
2.0–2.9	16
3.0–3.9	59
4.0–4.9	31
5.0–5.9	9

Table 3. Fat Limitations on Wholesale and Fabricated Cuts of Fresh Beef

Maximum Average Thickness of Surface Fat (inches)	Related Maximum Thickness at Any One Point (inches)
1.0	1.25
0.75	1.0
0.5	0.75
0.25	0.5

Source: USDA 1970.

Consistent with the breaker's normal procedure, each cut was trimmed to the dual requirements of a maximum fat cover of 0.75 inch at any point and an average fat cover of no more than 0.5 inch. These "fat cover tolerances" are slightly below the middle of the USDA's IMP Series 100 specifications as reproduced in table 3. The only control exercised by the research team was control over the pace of activity to insure each lean cut, piece of bone, and scrap of fat could be accurately weighed and identified with the correct carcass. The regular crew did the breaking via a conventional on-the-table breaking procedure.[2]

Equations (1) through (6) are estimated "cutability equations" from the generated data for selected dependent variables. In general, the explanatory variables—the variables that were used in the Murphey cutability equation—exhibit estimated parameters that are statistically significant. However, the coefficient of determination (R^2) for each equation is lower than a priori expectations, suggesting sources of variability not accounted for in the equations influence the yield of lean cuts. Standard errors for the estimated coefficients are shown in parentheses:

$$(1)\quad \begin{aligned} PT7PCW &= \underset{(1.4689)}{78.0116} - \underset{(0.0020)}{0.0057HCWT} - \underset{(0.3748)}{1.0000BFTHKNS} - \underset{(0.2295)}{0.3387KHP} + \underset{(0.0879)}{0.218REA}, \quad R^2 = 0.287; \end{aligned}$$

$$(2)\quad \begin{aligned} P7PCW &= \underset{(1.5473)}{46.8921} - \underset{(0.0021)}{0.0092HCWT} - \underset{(0.3948)}{1.3102BFTHKNS} - \underset{(0.2417)}{0.2763KHP} + \underset{(0.0926)}{0.4003REA}, \quad R^2 = 0.410; \end{aligned}$$

$$(3)\quad \begin{aligned} PT4PCW &= \underset{(1.7454)}{68.6375} - \underset{(0.0023)}{0.0113HCWT} - \underset{(0.4454)}{1.402BFTHKNS} - \underset{(0.2727)}{0.7791KHP} + \underset{(0.1045)}{0.2940REA}, \quad R^2 = 0.428; \end{aligned}$$

$$(4)\quad \begin{aligned} P4PCW &= \underset{(1.5441)}{43.5117} - \underset{(0.0021)}{0.0098HCWT} - \underset{(0.3940)}{1.2340BFTHKNS} - \underset{(0.2413)}{0.2882KHP} + \underset{(0.0924)}{0.3808REA}, \quad R^2 = 0.408; \end{aligned}$$

$$(5)\quad \begin{aligned} PT3PCW &= \underset{(1.1225)}{9.9971} + \underset{(0.0015)}{0.0045HCWT} + \underset{(0.2864)}{0.3958BFTHKNS} + \underset{(0.754)}{0.4289KHP} + \underset{(0.0672)}{0.0012REA}, \quad R^2 = 0.210; \end{aligned}$$

and

$$(6)\quad \begin{aligned} P3PCW &= \underset{(0.3877)}{3.3803} + \underset{(0.0005)}{0.0006HCWT} - \underset{(0.0989)}{0.0762BFTHKNS} + \underset{(0.0606)}{0.0119KHP} + \underset{(0.0232)}{0.0195REA}, \quad R^2 = 0.035. \end{aligned}$$

The variable names used in the analysis are $P7PCW$ = lean cuts from seven primals as percentage of cold carcass weight; $PT7PCW$ = lean cuts from seven primals as percentage of cold carcass weight, lean trim included;[3] $P4PCW$ = lean cuts from four major primals as percentage of cold carcass weight;[4] $PT4PCW$ = lean cuts from four major primals as percentage of cold carcass weight, lean trim included; $P3PCW$ = lean cuts from three minor primals as percentage of cold carcass weight;[5] $PT3PCW$ = lean cuts from three minor primals as percentage of cold carcass weight, lean trim included; $HCWT$ = hot carcass weight (pounds); $BFTHKNS$ = back fat thickness (inches); KHP = kidney, heart fat as percentage of carcass weight (%); and REA = ribeye area (square inches).

Equations (7) through (12) are estimated functional relationships with cutability as the dependent variable and yield grade (YG), to the nearest 0.1, as the single explanatory variable. The estimates of the slope coefficients are highly significant, but estimates of R^2 are relatively low. The estimated parameters for

[2] More detail on research design and analytical procedure is available from the authors.

[3] The lean trim was both 50-50 trim (50% lean) and 75-85 trim (75–85% lean).

[4] The four major primals are the loin, rib, round, and chuck.

[5] The three minor "primals" are the brisket, plate, and flank.

the yield grade variable indicate the change in cutout of lean boneless retail cuts per yield grade. The −0.81 to −1.15 range for all equations except equations (11) and (12), which deal with the three minor "primals," is revealing. Equation (7) provides an estimate of the relationship between lean cuts from the total carcass, including lean trim, and yield grade. Examination of the implicit ratio of the estimated parameter to the standard error indicates the estimate is highly significant. However, at a level of −0.8069 the change in cutability per yield grade would be less than the 4.6% reported by the USDA (1968). Equation (9), employing lean cuts plus trim from the four major primals, indicates the change in cutout from the four major primals would be 1.1457% per yield grade. Equations (8) and (10) give estimates of the slope coefficients between those of equations (7) and (9):

(7) $$PT7PCW = \underset{(0.4751)}{78.5163} - \underset{(0.1249)}{0.8069}YG, \quad R^2 = 0.264;$$

(8) $$P7PCW = \underset{(0.4643)}{47.3189} - \underset{(0.1221)}{1.1036}YG, \quad R^2 = 0.413;$$

(9) $$PT4PCW = \underset{(0.5640)}{64.8720} - \underset{(0.1483)}{1.1457}YG, \quad R^2 = 0.340;$$

(10) $$P4PCW = \underset{(0.4701)}{43.1566} - \underset{(0.1236)}{1.0737}YG, \quad R^2 = 0.394;$$

(11) $$PT3PCW = \underset{(0.3629)}{13.7039} + \underset{(0.0954)}{0.3203}YG, \quad R^2 = 0.088;$$

and

(12) $$P3PCW = \underset{(0.1183)}{4.1623} - \underset{(0.0311)}{0.0299}YG, \quad R^2 = 0.008.$$

Among the initial hypotheses that evolved from the results of the analysis is one that involves the nature of the data set. The Murphey equation was estimated from data on cattle ranging in class and quality from Canner and Cutter cows to Prime steers. Other analysts have suggested the USDA formulation would not necessarily be expected to "fit" a more homogeneous data set (Kauffman et al., Stringer et al.).

The lack of homogeneity does not appear to be sufficient as an explanation of the unexpected results, however. Examination of the literature reveals analyses conducted on more homogeneous groups of cattle that estimated differences in cutout between yield grades well above the estimates generated by the Purcell-Nelson study (Dinkel et al., Henrickson and Monroe, Stringer et al., U.S. Meat Animal Research Center).

A second and possibly more productive hypothesis rests in the implications of the thickness of fat cover allowed in the cutout tests. Figure 1 demonstrates, via the slope of estimated functions, the change in total carcass cutout per yield grade and the associated maximum allowable fat cover based on data from several studies. If the maximum fat cover allowed at any one point is 0.5 inch or less, the slope of the estimated function is negative and is 3.0 or more in absolute value. Each function is labeled by the maximum fat cover at any one point allowed in the study and by the name of the major author(s). The notation "CC" is used to denote the research conducted at the U.S. Meat Animal Research Center, Clay Center, Nebraska (U.S. Meat Animal Research Center). The notation "USDA" refers to the implicit functional relationship consistent with the USDA's announced differences in cutability across yield grades (USDA 1968). The other studies are, by major author, Dinkel, Henrickson, and Stringer and the Purcell-Nelson analysis.

The alternative studies underlying the information shown in figure 1 were also analyzed via the following model:

(15) $$R_i = \beta_0 + \beta_1 D_{1i} + \beta_2 D_{2i} + \beta_3 D_{3i} + \beta_4 D_{4i} + \beta_5 Y_i + \beta_6(D_{1i}Y_i) + \beta_7(D_{2i}Y_i) + \beta_8(D_{3i}Y_i) + \beta_9(D_{4i}Y_i) + e_i,$$

where i = ith weighted observation; R_i = lean retail cuts as percentage of carcass weight for ith weighted observation; Y_i = yield grade of ith weighted observation; D_{1i} = 1 if i is from the Stringer data, 0 otherwise; D_{2i} = 1 if i is from the Henrickson data, 0 otherwise; D_{3i} = 1 if i is from the Dinkel data, 0 otherwise; D_{4i} = 1 if i is from the Purcell-Nelson data, 0 otherwise; e_i = error; β_0 = intercept for the Clay Center data; β_1 through β_4 = coefficients for intercept dummies for the Stringer, Henrickson, Dinkel, and Purcell-Nelson studies, respectively; β_5 = slope coefficient for the Clay Center data; and β_6 through β_9 = coefficients for slope dummies for the Stringer, Henrickson, Dinkel, and Purcell-Nelson studies, respectively.

Equation (15) thus incorporates both intercept and slope dummies for the five sets of

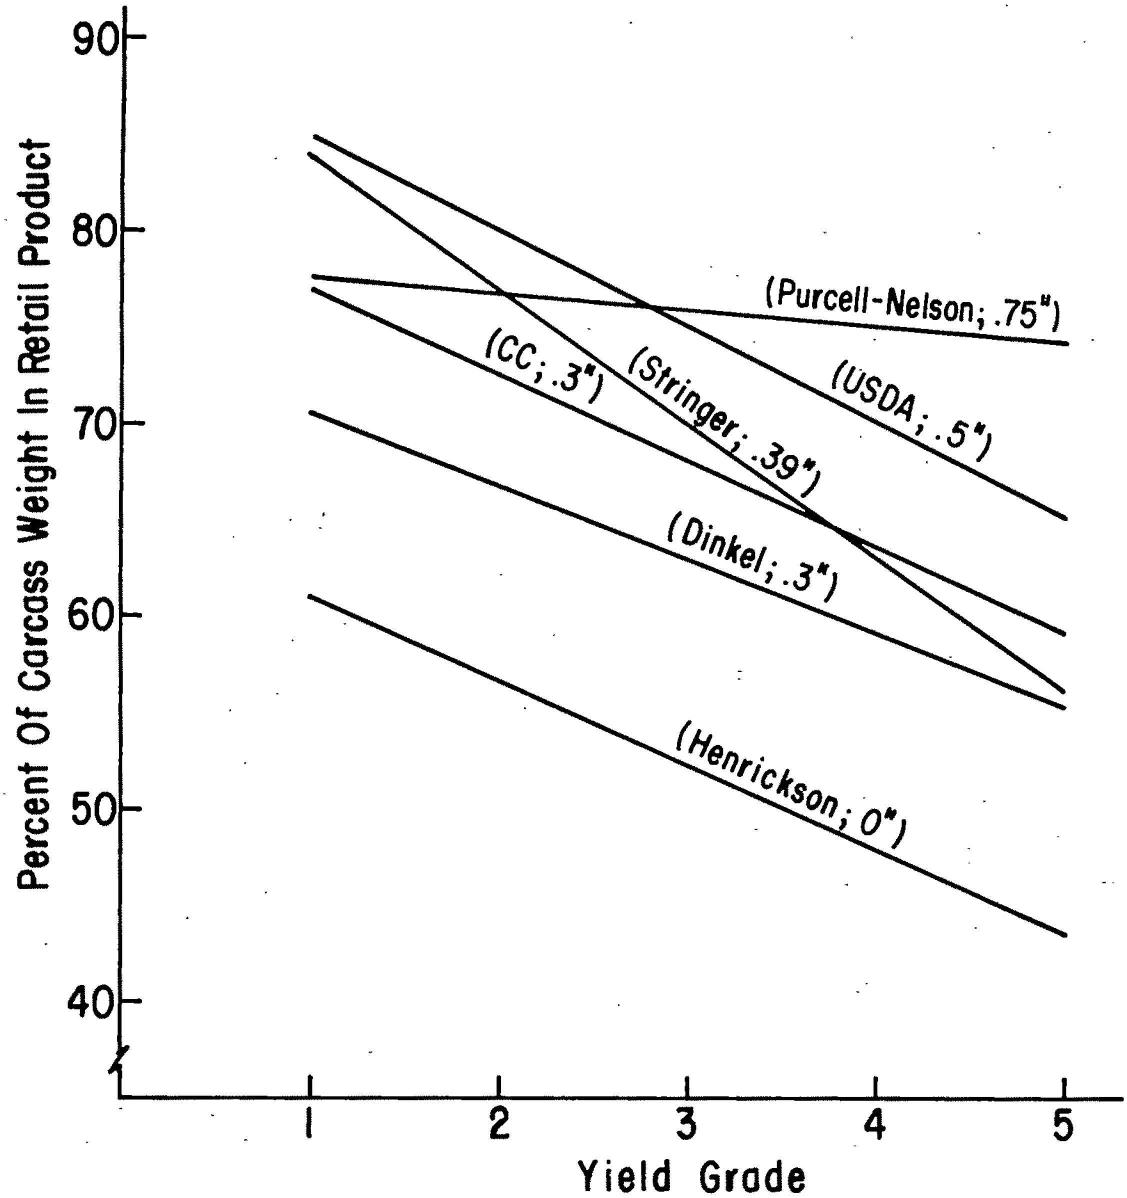

Figure 1. Estimated regressions for cutability on yield grade using mean observations from five different studies compared to the USDA relationship

data graphed in figure 1. With the Clay Center results established arbitrarily as a standard, the least squares estimates of the parameters in equation (15) provide numerical estimates of the differences in intercepts and slopes of the cutability equations across the five studies (U.S. Meat Animal Research Center). The function was estimated from a data set consisting of mean percentage of retail cuts as related to mean yield grades for all studies except the Purcell-Nelson study, where individual observations were used. Each mean was weighted by multiplying by the square root of the number of observations in the respective study. The results of the weighted least squares fit of the functional relationship are shown in table 4.

Several cautions are in order in evaluating table 4. First, the apparent level of quantitative measurement can be misleading. The data used in estimating the function do not justify accuracy to the extent implied by showing re-

Table 4. Regression of Retail Cuts as Percentage of Carcass Weight on Yield Grade

sults to several significant digits. In both the Dinkel and Henrickson studies, yield grades were not shown. Consequently, yield grades were calculated using reported measurements on carcass weights, backfat thickness, and area of the ribeye. The kidney and heart fat data were not reported and were estimated by the authors from marbling scores and quality grades as suggested by USDA standards.

Second, the total number of carcasses analyzed differed across the studies. There were forty-two mean observations from a total of 1,123 head in the Clay Center data (U.S. Meat Animal Research Center). In the Henrickson data, at the other extreme, a total of six means with six observations per mean were available. The observations were weighted to insure statistical soundness of the estimation procedure, but the range of the various measures in the data sets could have been affected by the number of observations.

The results in table 4, therefore, should be treated as approximations of how the different studies would have compared if such comparisons had been designed into the studies. The studies had other, if somewhat related, objectives and generated data on carcass cutability as part of the analyses.

Table 5 records the "net" intercepts and slopes derived from equation (15) for each study along with the maximum allowable fat cover used in the respective studies. The USDA guidelines, which call for a change of 4.6% in actual product per yield grade, are based on a maximum fat cover of 0.5 inch at any one point on the cuts from the chuck, round, loin, and rib, 0.25 inch elsewhere. No attempt was made to test directly whether the net parameters recorded in table 5 are significantly different from each other. Examination of the t-statistics in table 4 indicates whether the estimates from the different studies are significantly different from those based on the Clay Center data.

The functions in figure 1 and the results shown in tables 4 and 5 support the hypothesis that the allowable fat cover will influence relationships between cutability and yield grade. Given the physical characteristics of the beef carcass, the results are not surprising. The better carcasses (yield grade 1's and 2's) often have a fat cover that exceeds 0.75 inch at only a few points. Retail cuts from these carcasses receive little trimming and may carry a fat cover less than 0.75 inch (and the related 0.5 average cover). Conversely, the cuts from low cutability carcasses (yield grade 4's and 5's) are often trimmed back to meet the requirement of 0.75 inch cover at any one point and carry the maximum allowable fat cover. The cuts from the 4's and 5's thus carry a fat cover that is weighed with the cut and included in the weight of the "lean retail cuts." The result is an increase in the weight of cuts from the 4's and 5's relative to the cuts from the 1's and 2's. The slope of the linear cutability function is decreased as a result.

The level of fat cover allowed also is a factor in the second surprising result of the

Table 5. Net Intercept and Slope Estimates For Five Studies

Study	Maximum Fat Cover Allowed at Any One Point on Retail Cuts (inches)	Net Estimated Regression Parameters	
		Intercept	Slope
CC	0.30	81.176	−4.568
Henrickson	0	65.179	−4.325
Dinkel	0.30	73.823	−3.757
Stringer	0.39	90.908	−6.862
Purcell-Nelson	0.75	78.516	−0.807

Source: derived from table 4.

analysis—the low R^2's. The smaller the fat cover allowed, the more homogeneous will be the resulting set of measurements (weights) on the lean retail cuts. For given sample sizes, a regression equation will "fit" the more homogeneous data better and the R^2 statistic will be larger.

The Research Needs

The results reported herein are not presented as the final answer. They constitute a beginning in terms of motivating more research on cutability. Many research efforts on cutability exist in the available literature. Some of the more recent efforts have been directed toward developing a cutability relationship incorporating variables not included in the USDA equation. The recent effort by Kauffman and his colleagues incorporated marbling score into a cutability equation. Whatever the purpose, the analyses that have been conducted are characterized by two important similarities. First, in an effort to exercise experimental control, most tests have been conducted under conditions approaching "laboratory control." Second, trim has been very close ranging from complete removal of all surface and intermuscular fat to leaving no more than 0.5 inch of surface fat at any one point. Many of the experiments have allowed a fat cover at any one point of 1 centimeter (0.39 inch) or less.

Interaction with industry personnel suggests the allowable fat cover on retail cuts varies across producing firms and by type of buying institution. A fat cover of up to 0.75 inch at any one point is reportedly commonplace in the rapidly increasing boxed-beef method of distribution. Given variability in cutting practices, cutability equations developed from experiments with the allowable fat cover held constant will have limited applicability to industry decision makers. Research designed to treat the allowable fat cover on the final retail cuts as a controlled variable and to establish its statistical and economic importance is needed. A review of past studies suggests that the estimated slope coefficients in cutability equations will be comparable in magnitude when the allowable fat cover at any one point is less than 0.5 inch. The results of the analysis reported herein suggest estimated slope coefficients will be substantially different when the allowable fat cover at any one point moves up to 0.75 inch. Given the direct relationship between the magnitude of the slope coefficient and value differences between yield grades, this area merits further investigation.

A related phenomenon also appears to need further investigation. As the allowable fat cover changes, the per carcass yield of edible fat varies. The trim from a carcass is usually divided into categories such as 50-50 trim (50% lean) and 75-85 trim (at least 75% lean) and brought into estimates of value differences by yield grades. But the edible fat is ignored in the value estimates. During periods when the slaughter mix includes a relatively high percentage of cows and nonfed animals, the edible fat trimmed from fed beef carcasses becomes valuable as an input to ground beef. During 1975, with relatively high levels of cow and nonfed slaughter, yield grade 4 carcasses periodically traded at price levels above yield grade 2 carcasses of comparable weight and quality grade.

Summary and Conclusions

The move to required yield grading offers significant potential as a means of increasing pricing efficiency in the beef-marketing system. However, it is also one of the changes that continues to attract vigorous opposition. Much of the opposition emerges from the packers who express concern over increased costs of grading. Perhaps more important is the varying interpretation of the applicability of current yield grade standards under industry operating conditions.

Analysis of the data from cutability tests on 118 beef carcasses suggests the applicability of current yield grades may in fact be limited to rather specific industry practices. Fat cover on the retail cuts from the 118 carcasses was allowed to range up to 0.75 inch at any one point, the normal practice for the breaking plant in which the tests were conducted and well within the tolerances in the USDA's IMP Series 100. When alternative measures of cutability were regressed on yield grade estimates of the slope parameter were negative but 1.15 or less in absolute value. This compares with a value of 4.6 reported by the USDA as the expected change per yield grade in percent of lean retail cuts from the total carcass. Other studies with relative close fat cover tolerances, 0.5 inch or less at any one

point, generate estimates closer to the 4.6% figure.

If the move to required yield grading is to facilitate increased pricing efficiency in the beef-marketing system, the yield grade standards must meet the dual requirements of broad use and applicability. Given the results of this analysis, it would appear that meeting these requirements will require several developments.

First, additional research to clarify the relationship between fat cover tolerances and the change in cutout of retail cuts per yield grade must be completed. Varying and controlled levels of fat cover tolerances should be designed into the research to provide direct estimates of the influence of fat cover on functional relationships between cutout and yield grade. If possible, the research should be conducted in the same industry environment in which the yield grades must be used.

Second, and related, more information should be disseminated on what the industry operator can reasonably expect when using yield grades to buy or sell in his operating environment. Continued publication of a 4.6% change in cutout of retail cuts per yield grade damages the credibility of the grades to the entrepreneur who argues he never realizes this type of differential. Acknowledging the 4.6% differential will hold only for "closely trimmed cuts" leaves modification and adaptation of this norm to the individual entrepreneur. The result can be an array of interpretations that does little to move the industry toward the standardized pricing base needed for increased pricing efficiency.

Third, it appears that an attempt to modify the yield grade standards to include the value of edible fat is needed. Theoretically, the yield grade 2 carcass is more valuable than the yield grade 4 carcass of comparable weight and quality grade. During 1975 the increased ratio of cow and nonfed slaughter to fed slaughter bolstered the value of edible fat trimmed from the fed carcasses. This helped precipitate prices for the yield grade 4 carcass that periodically moved above prices for the yield grade 2's and 3's. Either incorporation of the value of edible fat into estimates of value differences across yield grades or explanations of the somewhat atypical price relationships would boost credibility and support applicability of the yield grades.

An Economic Evaluation of Alternative Peanut Policies

W. L. Nieuwoudt, J. B. Bullock, and G. A. Mathia

Three alternatives to the current peanut-price support, acreage-allotment program are considered. A linear programming framework is used to compare the effects of these policies on geographic location of peanut production, producer and consumer surplus, treasury costs, and value of allotments. Peanut production would expand in all areas except Texas under less restrictive production constraints. The largest expansion would be in Georgia and Alabama. Some version of the target price plan is considered to be a likely compromise program.

Key words: peanuts, policy, prices.

Peanuts are one of the few U.S. farm products receiving government price supports that have not been placed under the target price support legislation. The current peanut policy stems from the Agricultural Act of 1949 that established a minimum national acreage allotment of 1.6 million acres. Peanuts are supported between 75% and 90% of parity via a loan program, and peanuts not sold for edible use at the announced support price are acquired by the Commodity Credit Corporation (CCC).

Peanuts are not storable for long periods of time without refrigeration. Consequently, the CCC has disposed of its stocks by selling peanuts in the export market or for crushing purposes at prices considerably below acquisition prices. Peanut yields have increased more rapidly than edible use of peanuts leading to increased purchases by the CCC. This, coupled with depressed edible oil and meal prices during the late 1960s and early 1970s, led to rising treasury costs of the peanut program. Treasury costs in 1971 were $97 million (USDA 1974). As a result, the U.S. Department of Agriculture has proposed that peanuts be included in the target price legislation along with other agricultural programs. The peanut industry has so far successfully delayed efforts to scrap the existing program. However, efforts to change the program are likely to continue.

Peanuts are primarily produced in three areas of the United States: North Carolina-Virginia, Texas-Oklahoma, and Georgia-Alabama-Florida. The comparative advantage of growing peanuts differs among these areas due to cropping alternatives. Thus, policy modifications could have more impact on peanut producers in some areas than in others.

The purpose of this paper is to evaluate the effects of alternative peanut-price support policies on the geographic location of peanut production, farm income by regions, consumer and producer surplus related to peanuts, market prices of peanuts, and treasury costs. The analysis is based on costs and prices existing in 1973. The present policy is compared with the following alternatives: (*a*) free market, (*b*) 25% reduction in allotments, with peanuts grown on allotment acres supported at 16.2¢ per pound, and (*c*) prices supported at 15¢ per pound on 75% of current allotment acreage with no acreage restrictions or price supports on peanuts produced in excess of the reduced allotment. Comparisons are made between allotments that are transferable and nontransferable in alternatives (*b*)

and (*c*). Policy alternative (*c*) is a version of the target price plan proposed by USDA.

Analytical Framework

Programming Model

A linear programming model of the Duloy-Norton type was developed to determine the aggregate and regional impact of alternative policies (Duloy and Norton). The model incorporates negative-sloping product demand curves and positive-sloping labor supply functions with an allowance for producer risk aversion. The model includes fifty-nine resource situations in seven states: North Carolina, Virginia, Georgia, Alabama, Florida, Texas, and Oklahoma. Resource areas included in the analysis account for 97.8% of the current peanut acreage in the United States. The programming matrix contains 578 rows and 1,447 variables.

The complete programming model for the competitive case where consumer and producer surplus are maximized can be expressed as follows:[1]

$$(1) \quad \max Z = [X'W(A - 0.5BWX)] - [C'X] - [L(K_1 + 0.5K_2L)] - \left[\sum_{i=1}^{7} \phi_i (X'\Omega X)^{1/2}\right].$$

The first term measures total welfare, which is the integral of the linear product demand function $P = A - BWX$, where W is a diagonal matrix of average yields and X is a vector of aggregate acres.

The production costs are deducted in the second term ($C'X$), where C is a vector of production costs. Opportunity cost of labor is deducted in the third term, which is the integral of a positively sloping linear supply function $R = K_1 + K_2L$, where R is a vector of wages per hour and L is a vector of hours.

Costs associated with risk are deducted in the last term, where Ω is a variance-covariance matrix of gross activity returns and ϕ_i is an aggregate of risk aversion coefficients of all farms in the ith production area. Variances and covariances of gross income were calculated separately for each area because of agronomic and crop mix differences.

[1] A tableau format of this type of program is presented in Hazell and Scandizzo. The mechanics of this model have been discussed in previous issues of this *Journal* (Hazell and Partasarathy, Hazell and Scandizzo, Simmons and Pomareda). Thus, only a brief outline of the model is presented here.

Structure of Demand

National demand elasticities were taken from various sources (Brandow, Hildreth and Jarrett, Jellema, USDA 1966). For some crops, such as corn, elasticities were calculated as weighted averages of direct human and derived livestock demands. National demand slopes were based on the following elasticities: soybeans −1.17, wheat −0.24, corn −0.27, barley −0.21, cotton −0.23, grain sorghum −0.90, hay (Alabama) −0.36, sorghum hay −0.36, and alfalfa hay −0.36. Exports and imports of all crops except peanuts are assumed to remain constant at existing levels.

The magnitude of the objective function solution (equation (1)) is affected by the size of the elasticity coefficients used. However, the relative magnitudes of the objective function among program alternatives would not be affected greatly. Thus, the magnitude of elasticities is not of major concern here since the purpose of the analysis is measurement of relative impacts of program alternatives.

Regional demands for all products except peanuts are highly elastic since their share of national production is small and supply outside the region is responsive to price changes. Regional demand slopes were derived from national demand slopes using a procedure suggested by Kutcher. The estimated regional demand elasticities (at 1973 production and prices) are about four times larger than national demand elasticities.[2]

The demand for peanuts has three components, namely, edible, crushing, and export. Estimates of demands for edible and export uses of peanuts were derived from secondary sources. The crushing demand was estimated directly. According to previous studies (Badger and Plaxico; Shafer, Nichols, and Branson; Reagan; Song), the demand elasticity for edible peanuts is about −0.25.

The export demand elasticity was estimated by the approach outlined by Johnson using demand and supply elasticities in the rest of the world. This procedure yielded an estimate of export demand elasticity for U.S. peanuts of −32.

A demand curve for crushing peanuts (linear in original values) was estimated by least squares regression using data for the period 1951–73 as follows:

[2] In all policy experiments with the programming model, the solutions obtained with the estimated elasticities were compared with solutions of a fixed price demand specification for all products other than peanuts.

$$(2) \quad P_{cr} = 0.375 + \underset{(5.0)}{1.457}P_{co} - \underset{(1.9)}{0.6147}Q_c + \underset{(3.3)}{0.001367}I, \qquad R^2 = 0.76,$$

where P_{cr} = price of peanuts for crushing (cents per pound), P_{co} = cottonseed price (cents per pound), I = disposable income per capita (dollars), and Q_c = crushed peanuts per capita (pounds). t-ratios are shown parenthetically.

The price flexibility of crushed peanuts at mean levels is estimated at −0.24. The price elasticity is probably larger in absolute value than −4.2 (the inverse of the price flexibility) since cottonseed and soybeans are substitutes for crushing peanuts.[3] The positive income coefficients can be explained by the fact that peanut oil is used for high quality salad or cooking oil.

Labor Supply

Separate regional labor supply functions for each month were built into the model. Labor constraints for any one month can be relaxed by hiring more labor at increasing wages as specified by the labor supply function. Seasonal and regional supply elasticities incorporated in the programming model are taken from Glover and from Tyrchniewicz and Schuh. Labor supply elasticities used for the Southwest were 1.25 for May to June and 2.12 for July to October. For the Southeast, including North Carolina-Virginia, labor supply elasticities of 1.03 for May to June and 1.75 for July to October were used.

Monthly labor available in each state was limited to the average monthly employment (regular labor) during the year. The supply of regular labor was assumed to be perfectly elastic at the minimum wage of $1.50 per hour up to the average employment level. Beyond this point, labor supply is assumed to be characterized by the above elasticities. Information on high school and college vacations was used to adjust the constant terms of supply functions. The opportunity cost of labor, i.e., area under the labor supply function, was deducted in the objective function. This is a nonlinear constraint that was linearized according to the method described by Duloy and Norton.

[3] A price elasticity is equal to the inverse of the price flexibility, only when all cross elasticities are 0 (Jellema). Song reported crushing demand elasticities between 9 and 26, but his results were significant only at the 50% level.

Risk, Production, and Cost Data

Price and yield risks are included in the model to account for year-to-year variability about the income levels reflected in the budgets. The risk component of the model is an effort to account for the realities of dynamics within the context of a static programming model. This study does not exploit the power of the Duloy-Norton model with respect to analysis of the risk aversion behavior of producers. The risk component of the model is used to improve the descriptive capacity of the model. No effort is made to study the risk behavior of producers or to incorporate the specific risk characteristics of alternative programs.[4]

Variance-covariance risk matrices are based on gross incomes per acre of the three main peanut-producing areas for the years 1967–72.[5] Variance-covariance matrices are approximated using the mean absolute deviation method described by Hazell and Scandizzo.

The more important peanut-producing counties in each state are included as separate resource situations. Other counties are pooled into homogeneous resource areas for each state based on soil and other characteristics. With the aid of soil maps and agronomic expertise, land considered suitable for peanut production was programmed in the model. A comparison of actual peanut allotment acreages to the total potential peanut acreages (shown in brackets) is as follows: North Carolina—165,405 [474,106], Virginia—102,000 [123,107], Alabama—197,000 [423,725], Georgia—507,490 [981,121], Florida—55,000 [117,178], Oklahoma—116,350 [330,000], and Texas—311,000 [689,600].

Detailed crop budgets were obtained for the three main producing areas of North Carolina-Virginia, Georgia-Alabama-Florida, and Texas-Oklahoma. These budgets were supplemented with information on relative magnitudes of cost items contained in other budgets (Freeman, McArthur, Strickland and Harwell, USDA 1966). The program was formulated to account for differences in small and large farms (Georgia-Alabama) and irrigation and dryland crops (Texas-Oklahoma). Allowances were made for nitrogen fixation by

[4] Income variability is likely to vary between programs, e.g., farmers would expect lower price variability under a price-support program than under a free market arrangement. However, the programs are assumed to have a neutral effect on risks of producers.

[5] Trend was eliminated from gross income per acre data.

peanuts and soybeans. A value for grazing was assigned to crops such as wheat in Oklahoma. Average yield data for fifty-nine resource areas obtained from crop-reporting offices were included for the three years (1971–73).

Model Results

Base (1973) cropping acres compared with model estimates, applying risk aversion values of $\phi = 0$, 1, 2, 2.5, and 3, are shown in table 1.[6] A value of $\phi = 0$ implies that producers are neutral to risk, and higher values of ϕ indicate that producers are more risk averse. Squared simple correlations between actual and predicted crop acres of state totals are, respectively, 0.864, 0.888, 0.937, 0.916, and 0.899.[7]

[6] To save space, crop acres are presented in table 1 only for those crops that changed with different ϕ values. Peanuts and tobacco came in at the maximum of their acreage allotments and were not affected by different ϕ values because of relatively high shadow prices on allotments.

[7] Little significance is placed on the value of ϕ selected. It is used here as a method of fine-tuning the predictive ability of the model. A premium was placed on accuracy, although the differences between several of these correlations are probably not statistically significant. A value of $\phi = 2$ produced the most consistent set of predictions when compared with actual production. Hazell and Partasarathy comparing alternative demand specifications, reported that $\phi = 1.5$ and 2.0 provided the best description of cropping patterns and prices of short cycle crops in Mexico. Simmons and Pomareda favored $\phi = 0.5$ for export crops and $\phi = 1.0$ for all crops.

Base crop prices (1973) are compared with dual prices as generated in the model in table 2. Squared correlation coefficients between base and dual prices for $\phi = 0$ and $\phi = 2$ are, respectively, 0.971 and 0.980.[8]

Dual wages generated by the model are presented in table 3. The wage rates increase to \$3 per hour (first column) in July and August because tobacco, a labor-intensive crop, is harvested in August.

Shadow prices on the present peanut acreage allotments, presented in table 4 (column

[8] A dual price is the shadow price of that segment on a demand function that is selected in the optimum solution (Egbert and Kim). A dual price thus provides a better estimate of the "true price" as determined in the optimum solution than the primal price that is calculated *ex post* when demand curves are segmented into steps.

Table 2. Base Prices (1973) Compared with Endogenously Generated Prices

Crop	Base[a]	$\phi = 0$	$\phi = 2$
Soybeans	5.722	5.327	5.407
Wheat	3.323	3.424	3.505
Corn	2.50	2.45	2.54

Alabama hay	46.9	63.04	57.7
Sorghum hay	32.0	46.8	44.0
Alfalfa hay	48.0	44.6	45.35

[a] Cotton price is ¢/lb., hay prices are \$/ton. All other prices are \$/bu.

Table 3. Dual Wages of Model Solution

Month	North Carolina, Virginia, Georgia, Alabama, Florida	Oklahoma, Texas
	$/hour	
May	2.56	1.83
June	2.16	1.71
July	2.49	1.66
August	3.06	1.50
September	1.63	1.76
October	1.81	2.43

2), measure the annual per acre economic rent on peanut allotments to farmers. Shadow prices are consistent with observed rental values of allotment leases.[9] The shadow prices reported in table 4 are weighted averages of the fifty-nine resource areas included in the model.

The high shadow price (in cents per pound) in Georgia indicates that this state has a comparative advantage in peanut production relative to other areas. Peanut yields per acre in Georgia are about the same as in the North Carolina-Virginia area, but yields of alternative crops such as corn and soybeans are lower in Georgia.

The lowest allotment rent is for dryland peanuts in Texas (table 4). Shadow prices (cents per pound) in North Carolina are close to that of Virginia because peanuts are grown on either side of the common boundary between the two states. Slightly higher peanut yields and lower returns on alternative crops yield relatively high shadow prices on Oklahoma dryland peanuts.

[9] In policy experiments with the programming model, $\phi = 1$ was adopted for North Carolina-Virginia and $\phi = 2$ was used for all other states because peanut acreage appears to be sensitive to higher ϕ values in alternative policy solutions when the risk neutral case is compared with risk averse solutions.

Comparison of Current Program with Alternative Programs

Simulation of crop production patterns under the existing peanut program is now compared with model simulation solutions of alternative policies. Tables 5 and 6 show explicit estimates of several dimensions of program impacts. However, the relative magnitude of these estimates across programs is of more significance than the absolute levels. For example, the current program has an estimated treasury cost of $35 million and an estimated social cost of $67 million for the 1973 crop year (table 5, column 1). No claim for the precision of these estimates is made. However, the consistent estimation procedures used across policy alternatives should provide a good measure of the relative impact each alternative has in the various dimensions considered.

Social cost is measured in dollars of goods foregone because of a nonoptimum output. The reader is referred to Tweeten and Tyner for a more detailed discussion of social costs and to Marshall for a discussion of producer and consumer surplus.

Free Market Solution

This policy is simulated by using the maximization of producer and consumer surplus from

Table 4. Shadow Prices on Peanut Allotment Based on Model Solutions Compared with Observed Annual Allotment Rental Values

Area	Shadow Price	Allotment Rental Value[a]	Shadow Price[b] (¢/lb)	Allotment Peanut (acres)

[a] Capital loss is an upper bound except for policies (3a) and (3b).

peanuts as the objective function of the model. This leads to the same result as a competitive market framework. A free market policy would lead to a 34% expansion in peanut acreage from current levels. This increase is due largely to an expansion of peanut production in the Georgia-Alabama-Florida area (table 6, columns 1 and 2). An increase in peanut acreage of 81% in this area gives some idea of these states' comparative advantage in peanut production.

By contrast, peanut acreage in Texas is reduced considerably. Peanut production in Oklahoma increases, demonstrating that although peanut yields are lower in Oklahoma than in the Southeast this state has a comparative advantage in peanut production. Peanut production expands in North Carolina and remains about the same in Virginia. The expansion in peanut production in the Southeast is accommodated largely through a reduction in area planted to soybeans.

Endogenously generated free market peanut prices in edible, crushing, and export markets were estimated to be about 3¢ per pound lower than base prices (table 5, columns 1 and 2).[10] Most of the increased production would be exported. Treasury and social costs of the free market solution are 0.[11]

Abolishment of allotments may entail a loss to farmers because allotments currently can be leased or sold. However, producers will not lose the full allotment rental value. The loss to producers is represented by the difference between the support price and free market price that is estimated to be 3.2¢ per pound (table 5). In states where rental values exceed 3.2¢ per pound, the difference between the rental rate and 3.2¢ is an addition to land rent. The value of land suitable for peanut production is then expected to increase in these areas.[12] The

[10] Price differences reflect grade differences because only the larger peanuts are exported.

[11] In contrast to a free market solution, producer surplus was maximized in an alternative solution (not presented) by equating marginal revenues of edible, crushing, and export demand to marginal cost of peanut production as determined in the program. Predicted peanut acres were about the same as under the current allotment program, but producer surplus and social cost increased substantially compared to the current program.

[12] Allotment value is excluded from land values in this context. It is also realistic to assume that differences in current allotment

possible rental loss to farmers in the free market solution is estimated at $92.2 million if gain in land rent is considered. If this is capitalized at 20% because of present uncertainty concerning continuation of the allotment system, capital loss to producers is estimated at $461 million.

Producer surplus, measured at base prices for all products except peanuts, falls slightly under a free market policy compared to the current program from $753 million to $719 million (table 7). Producer surplus in Georgia falls by only $4 million, in Oklahoma it remains the same, and in Florida it increases (table 7, columns 1 and 2) because of an expansion in peanut production.[13]

rental rates between counties are largely attributed to differences in land quality. Any input factor, however, with a positive supply captures a rent.

[13] It is important to test the sensitivity of policy solutions regarding alternative demand specifications. In an alternative model specification, consumer and producer surpluses of peanuts were

Total	753	719	716	756	747	783

The switch to a free market for peanuts would lead to a 15% reduction in peanuts grown in Virginia and about a 75% reduction in Texas. Peanut production would expand the most in Georgia and Florida.

Twenty-five Percent Reduction in Allotment Acreage

This program considers that allotments for individual farms are reduced by 25%, while peanut prices are kept at base levels. The purpose of such a program is to reduce treasury cost since no cost is incurred on edible peanuts, which comprise about 60% of the total production. By reducing allotments by 25%, treasury costs decline by 75% to $8.5 million.

If allotments are not transferable between production areas, producer surplus from peanuts declines by $66 million or 25%. However, producer surplus of all crops declines only by $36 million when all prices are kept constant (table 5, columns 1 and 3a). The smaller decline in total producer surplus is due to an expansion of other crops on land released from peanut production. The reduced peanut acreage was largely replaced by soybeans in the southeastern states including North Carolina (table 6, column 3a). "Capital loss" as a result of smaller allotments is estimated at $185 million. Producers lose the full rental rate plus land rent from peanut production on 25% of their allotments. According to table 7 (column 3a) producer surplus in all states falls. The social cost of $85 million for this policy is higher than that of the present program because of smaller acreage allotments.

If allotments are assumed to be transferable in the above program, a regional shift in peanut production would occur.[14] Farm income increases relative to the present level because peanuts move to areas with a comparative advantage in peanut production (table 7, column 4).[15] Although peanut production is reduced, the social cost of $46 million (table 5) for this policy is smaller than that of the current program because allotments are transferable. The estimated free market price for allotments is 5.6¢ per pound with this alternative. This compares with 5¢ per pound if the current program were continued but allotments were made freely transferable. The reduction in allotments leads to higher allotment rental values but lower land rents.

maximized assuming that prices of all other products are fixed. Predicted peanut acres for both cases are remarkably similar. The model in which all demands except peanuts are assumed perfectly elastic predicts a smaller decline in peanut acreage in Texas and a smaller expansion in Oklahoma.

[14] Peanut acreage allotments are currently transferable within county borders. The transfer, however, occurs on a yield basis, ensuring that total production remains the same. For example, if one acre allotment is transferred from a farm with a 1,500 pound yield of peanuts per acre to a farm with a 3,000 pound yield, the latter farm is entitled only to one-half an acre of allotment.

[15] Income from the sale of allotments is not included. Hoover and Efstratoglou Todoulos discuss how owners and renters are affected when transfers are permitted.

Target Price Plan

In this program, acreage allotments of individual farms are reduced by 25%. This acreage would be sufficient to meet domestic edible needs. Farmers would receive a target price of 15¢ per pound on peanuts produced under allotments. This program allows for unrestricted production in excess of the reduced allotment that would not be eligible for price supports.

This program will require the creation of some agency with monopoly power in selling peanuts for edible uses if users of edible peanuts are to pay 15¢ per pound for peanuts. Users of edible peanuts will otherwise purchase nonsupported peanuts at a lower price. This would lead to treasury costs for this program that are much higher than those shown here. This is a requirement of this program that apparently has not received much attention.

With a 15¢ per pound target price on allotment peanuts and unrestricted production sold in the free market (without support), peanut acreage expands 44%. Exports increase about threefold. Expansion in most states is similar to that predicted under the free market policy alternative, except that peanuts are "protected" in states with a comparative disadvantage, such as in Texas (table 6, column 4a). The 15¢ support price on the allotment acreage is a subsidy that acts through the marketing mechanism, stimulating peanut production above the free market level (table 5, columns 2 and 4a). Generated export and crushing prices of 13.1¢ and 11.9¢ per pound are similar to those of the free market solution (table 5, column 4a). These prices also correspond to the 15¢ target price and 12¢ floor price plan recently suggested by the USDA.[16]

Producer surplus from all crops declines by only $5 million compared to the present allotment system (table 5, column 4a). The small decline in producer surplus is due to an expansion in peanut production and the maintaining of a higher price in the inelastic edible market. Producer surplus increases in Georgia, Oklahoma, and Florida but falls slightly in the other states (table 7, column 4a).

The treasury cost of $4 million is less than the current program because allotments are reduced, and the social cost of $26 million is less than for the current allotment program due to unrestricted production. "Capital" loss as a result of smaller allotments and low support price is estimated at a maximum of $246 million. As explained for the free market policy, the increase in producer surplus from expansion in peanut production is not included in this number.

The target price plan would result in expanded peanut production in all areas except Texas. Peanut production in Texas declines by more than the 25% allotment reduction. Some areas of Texas would choose not to use their allotment if this program were implemented. Total peanut production under the target price plan would be about the same as for the free market alternative.

If allotments are transferable, predicted peanut acres are almost identical to that of a free market policy. Producer income is $2 million higher than that of the current program, and the social cost of $9 million is relatively small because of freedom in production and transferable quotas. The higher support price is simply an income transfer to farmers. The estimated free market price of allotment rental values is 1.9¢ per pound for this program alternative, which is equal to the difference in the support price (15¢ per pound) and the weighted average of export and crushing prices (13.1¢ per pound).

Conclusions

Three alternatives to the current peanut policy have been evaluated: (*a*) a free market alternative, (*b*) a 25% reduction in allotments with prices supported at 16.2% per pound, and (*c*) a target price plan where allotments are reduced by 25%, and peanuts produced on allotment acres are supported at 15¢ per pound; production in excess of allotment is permitted but receives no price support.

The "most desirable" program depends on the weights attached to the various impacts of alternative programs. None of the programs is clearly "best" in all dimensions. Policy makers and affected producers will have to decide which of the alternatives (including those not evaluated here) is most desirable given the realities of the political constraints.

Producers are most concerned about producer incomes and potential capital losses associated with allotments. Policy makers are likely to be most concerned about levels of treasury costs and to a lesser degree about

[16] During the middle of 1975, the USDA suggested a 15¢ target price on 75% of acreage allotments with a 12¢ floor price on unrestricted production.

social costs of alternative programs. The free market alternative is clearly most desirable from an economic point of view if income distribution problems are ignored. However, producers are likely to oppose strongly this alternative because of the sizeable capital losses involved and because of its potential effects on relocation of peanut production. The reader is referred to Tullock for an interesting discussion about the problems of capital losses caused by terminating or reducing government programs.

A 25% reduction in allotments with no open-end production may be attractive to policy makers since it reduces treasury costs. However, it is politically unattractive because it further limits producer choices and also has higher social costs than the current program. Peanut producers are likely to oppose this program because of reduced income plus capital losses in reduced allotments.

The target price plan greatly reduces treasury costs and social costs. It increases producer surplus and has very little effect on total farm income relative to the current policy. Capital losses from reduced allotment values are only about 53% of what they would be if a free market alternative is selected. Thus, some version of the target price plan appears to be a likely compromise policy.

This study has the limitations of being a comparative statics analysis of a dynamic problem. Further work is needed to evaluate the effects of program changes on farm size and the structure of the peanut-processing industry. These analyses were beyond the scope of this study.

Estimating the Influence of Service Quality on Transportation Demand

Marc A. Johnson

Following a theoretical justification for considering service quality as a demand determinant based upon conventional derived demand analysis, an empirical procedure is developed for estimating the response of demand and modal selection probability to changes in service quality. The estimation technique suggested is similar to that used in the measurement of hedonic price indices, permitting a subjective evaluation of quality factors by shipping managers. An empirical demonstration suggests that transport demand responsiveness to transport service quality is inelastic for country grain elevators.

Key words: modal selection probability, service quality, transportation demand.

An argument often heard in Interstate Commerce Commission railroad abandonment hearings is that deterioration of railroad service quality has discouraged traffic sufficiently to cause line enterprise failure. Sensitivity of transportation demand to variations in service quality can be empirically tested. If transportation demand truly is sensitive to service quality, then (*a*) transport price elasticity estimates ignoring service quality will be biased and misleading, (*b*) simple traffic forecasting techniques will generate unreliable results, and (*c*) measurement of this sensitivity will provide a basis for adjustment of service standards to more effectively and efficiently serve shipping customers.

Empirical work with freight transportation demand is new enough that its chief value lies in developing a stock of methodological and statistical experience. This article offers a method for estimating the influence of transportation service quality upon transportation demand. The method is demonstrated empirically for grain shipments from country elevators. The empirical analysis illustrates the method. Further empirical experience with service quality elasticities is required before these parameters can be used confidently to improve traffic-forecasting procedures and to evaluate optimal service standard adjustments.

Perle attempted to estimate short-run, own, and cross-price elasticities of demand for railroad and motor carrier services using time-series data. Poor statistical results led Perle to conclude that price behavior provides neither a sufficient nor major answer to intercarrier competition. Perle recognized the potential influence of nonprice characteristics of movement and service but only as longer-term determinants of secular change associated with intermodal competition.

Subsequent theoretical contributions suggest the short-term significance of nonprice, transportation characteristics. Craig developed a behavioral model for transportation mode selection using price and service quality characteristics jointly. Managers measure attributes of each mode by levels of anxiety and select the mode that minimizes anxiety.

Kolsen developed a managerial utility model for selecting transportation modes involving price-quality combinations. Quality of transport service is added at a cost, and users are willing to pay higher prices for higher service quality. Service quality attributes are valued subjectively. Profit maximizing managers seek to equalize marginal subjective value with marginal cost of quality increments.

Marc A. Johnson is an assistant professor of agricultural economics at Oklahoma State University, Stillwater.

Paper No. J-3049 of the Journal Series of the Oklahoma Agricultural Experiment Station, Stillwater. This research was supported by the Michigan Department of State Highways and Transportation and the Agricultural Experiment Stations of Michigan and Oklahoma. The author acknowledges the helpful suggestions of William J. Haley, Michael S. Salkin, Gary M. Mennem, and three *Journal* reviewers.

A useful notion inherent in both the behavioral and quasiutility approaches to derived demand is implicit valuation by shippers of an array of service quality alternatives, whether monetary valuation is directly measurable or not. This notion suggests an approach to service quality elasticity estimation that is applicable where dollar costs of incremental service standards are not readily identifiable.

Market research in several European countries has revealed that shippers do recognize relative service quality attributes between modes (Bayliss). Service attributes that have been shown to influence modal choice are certainty of delivery time, speed, and product safety. However, Bayliss concludes that while market research reveals which quality characteristics are perceived to have value the approach lacks the ability to compare relative intensities of influence. Consequently, one may hear shippers complain of poor service quality, while relative capabilities of alternative modes are insufficient to cause a change in firm shipping patterns.

Empirical attempts have been made to estimate the probability that a firm will select a particular mode (Bayliss). However, modal selection probability models have not given broad attention to service quality characteristics. Typically, the influence of only physical movement characteristics is considered, such as commodity value per unit, consignment weight, and movement distance.

There appears a need to expand transportation demand and modal selection probability models to consider nonprice determinants treated in conceptual approaches and revealed in market studies. Following a brief theoretical justification for considering service quality as a demand determinant based upon conventional derived demand analysis, an empirical procedure is developed for estimating the response of demand and modal selection probability to changes in service quality. The technique is designed to estimate the quantitative influence of quality factors upon freight transportation demand, even when some of the quality factors can be evaluated only subjectively by shipping managers. A demonstration of the procedure for outbound railroad shipments of grain from Michigan country elevators serves to illustrate the use of the technique and to estimate first approximations of service quality elasticities for grain movements.

Theoretical Model

Freight transportation is an input to commodity production for which value is derived from the demand for final products at specific locations and times. Each transportation input for movements to a particular location can be described as a bundle of many rate and service quality characteristics. Service quality is an aggregate term referring to the bundle of nonprice characteristics of transportation inputs that influence their usefulness in the production process. Examples include transit speed, product safety, and service reliability. Individual service quality attributes may substitute for price characteristics when shippers select transportation modes. Service quality characteristics may be built explicitly into models of derived demand for railroad and motor carrier services, similar to the manner in which price is conventionally treated.

Assume a short-run production function of any firm producing a particular commodity of the general form

$$(1)\quad y = f(x_i, x_j | x_p) \quad \text{for } i = 1, \ldots, n, \text{ and } j = 1, \ldots, m,$$

where y = output quantity of the commodity produced, x_i = quantity of variable plant input i, x_j = quantity of transport service of mode j, and x_p = quantity of composite durable plant input. Transportation inputs (x_j), in units of tons or ton-miles moved per period, inject time and place utilities into goods and services produced by the firm. Assuming a competitive product market and factor markets that are either competitive or regulated to provide the firm with no control over input prices, the solution of necessary profit-maximizing conditions for the unknown input quantities provides definitions of derived demand functions for variable plant and transportation input flows:

$$(2)\quad x_i = d_i(p, r_i, r_j) \quad \text{and} \quad x_j = d_j(p, r_i, r_j),$$

where p = product price, the r_i's = variable plant factor prices, and the r_j's = effective transport prices. The quantity demanded of each input is dependent upon the output price and all factor prices.

Effective transportation prices include more than published transport rates. Effective prices are total unit costs incurred by users of transportation inputs. Examples of nonrate costs are the inventory costs associated with goods in transit, the cost of storing safety

stocks as insurance against unreliable service, and the costs of uninsured damage and loss. Effective transportation price for mode j may be defined as the published freight rate (r_{jp}) plus costs associated with an array of s service quality characteristics (r_{jq}). The nonprice consumption cost (r_{jq}) is dependent upon the levels of service quality characteristics (q_{jk}, $k = 1, \ldots, s$) offered by mode j. Thus, effective transport price for mode j appears as

$$(3) \qquad r_j = r_{jp} + r_{jq}(q_{j1}, \ldots, q_{js}).$$

Substituting the effective transport price definitions in equation (3) into the input demand functions in equation (2) reveals that total freight service demanded from mode j is determined by the magnitudes of product price, plant factor prices, published transport rates, and costs of using service of particular quality levels:

$$(4) \quad x_j = d_j[p, r_i, r_j(r_{jp}, q_{j1}, \ldots, q_{js})].$$

The rate of change in quantity of transport service demanded from mode j as own effective price (r_j) changes is $\partial x_j / \partial r_j$. The rate of change in effective transport price as service quality attribute k changes is $\partial r_j / \partial q_{jk}$. Thus, the rate of change in quantity demanded as service quality attribute k changes, operating through the effective price mechanism, is

$$(5) \qquad \frac{\partial x_j}{\partial q_{jk}} = \frac{\partial x_j}{\partial r_j} \frac{\partial r_j}{\partial q_{jk}}.$$

Service quality elasticity of demand equals this rate of change in demand multiplied by the ratio of quantitative quality and demand levels (q_{jk}/x_j). Similarly, the rate of change in the quantity of transport service demanded from mode j as service quality characteristic k of mode g changes is

$$(6) \quad \frac{\partial x_j}{\partial q_{gk}} = \frac{\partial x_j}{\partial r_g} \frac{\partial r_g}{\partial q_{gk}} \text{ for } j, g = 1, \ldots, m.$$

Cross service quality elasticity of demand equals this rate of change multiplied by q_{gk}/x_j.

Empirical Models

Theoretical results suggest that service quality changes influence the quantity of modal service demanded by a shipper firm through the effective price mechanism. Direct estimation of derived demand functions for freight service would require quantitative measurements of attributes associated with individual service inputs and costs of consumption accompanying these service levels. The latter category of information is difficult to quantify, increasingly so at finer levels of disaggregation. Indirect estimation involving measurement of the relationship between quantities of service demanded of a particular mode and levels of service quality characteristics reveals implicit shipper valuation of transportation performance. This result suggests the use of an econometric procedure similar to that used by Griliches to measure hedonic price indices.

Two types of demand relationships are composed for use in answering different types of questions. First, ordinary derived demand functions express total quantity of services demanded of a particular mode as a function of product and effective factor prices. Adjustments for individual firm and shipment characteristics are required to isolate service quality influences. These functions are useful for transportation companies seeking optimum service levels and for shippers and communities determining terms of trade in transport service contracting.

The general model of derived demand for transport services from mode j appears as

$$(7) \quad x_j = \alpha + \beta_1 p + \sum_i \beta_i r_i + \sum_j \beta_j r_{jp} + \sum_j \sum_k \beta_{jk} q_{jk} + \sum_l \beta_l w_l + \epsilon_j,$$

where x_j = quantity of service demanded of mode j, p = product price, r_i = price of variable plant input i, r_{jp} = published or market freight rate for mode j, q_{jk} = quantitative level of service attribute k for mode j, w_l = magnitude of firm or shipment characteristic l, and α and β = parameters. Regression coefficients measure the isolated influence of associated variables upon the level of transport demand. In particular, service quality coefficients (β_{jk}) are defined as in equations (5) and (6) of the previous section. Service quality coefficients measure the magnitude and direction by which the quantity of transport service demanded changes with marginal changes in service quality levels.

Second, modal selection probability functions relate quality of service to the probability that a randomly selected firm will use services of a particular mode. Again, isolation of service quality influences requires adjustments

for individual firm and shipment characteristics. Modal selection probability results can be used directly in traffic forecasting to determine the proportions of future traffic generations that will move by particular modes under particular service quality conditions.

The modal selection probability estimator incorporates the same independent variables with a different dependent variable form. Probability of selecting services from mode j (P_j) is limited to the range $0 \leq P_j \leq 1$. Direct estimation would force estimation with a limited dependent variable. Classical linear regression models are potentially inappropriate when the dependent variable is bounded and the error term is not. To remedy this problem, logit analysis may be used. The logit transformation may produce heteroskedasticity in estimate errors (Theil). Regression results should be checked for the presence of this problem.

The general model for the probability of selecting mode j appears as

$$(8) \quad \ln \frac{P_j}{1 - P_j} = \delta + \gamma_1 p + \sum_i \gamma_i r_i + \sum_j \gamma_j r_{jp} + \sum_j \sum_k \gamma_{jk} q_{jk} + \sum_l \gamma_l w_l + E_j,$$

where δ and γ = parameters. Regression coefficients measure the percentage of change in the ratio of the probability of selecting mode j to the probability of selecting some other mode caused by unit changes in demand determinants.[1] Partial elasticities of modal selection probability are obtained by multiplying the respective regression coefficients by the observed level taken by the attribute. Elasticities of modal selection probability represent the percentage changes in modal selection probability resulting from 1% changes in individual demand determinants. Independent variables are similar for the two types of models, assuming that relative and total modal service demands are subject to similar influences.

Some caution must be taken in selecting quality variables, functional form, and data base for estimating either model type. The essential weaknesses of passenger transportation demand studies have been summarized by Quandt in four categories. Three of these problematic categories are relevant in freight transport demand investigations. First, all important demand influences must be considered explicitly to avoid model specification error by omitting variables. Second, the proper functional form must be used in estimation to avoid model specification error by misspecified functional form. Finally, data should be disaggregated to the firm level, within a commodity class, to estimate coefficients useful in decision making.

A Demonstration: Grain Movements

Measurement of transport demand determinants is illustrated using a cross-section sample of total annual outbound grain shipments from individual grain elevator firms in Michigan. Average final product prices (or margins) and average variable plant input prices were considered constant across firms during the single sample year 1973. Normal seasonal product, input, and motor transport price fluctuations did not affect total annual shipment volumes. Published rail freight rates did not vary substantially during the period, leaving the variable to behave as a constant. Under these realistic price constancy conditions, the variation in quantity of railroad service demanded by the individual firms depends only upon the variation in service qualities of railroad and motor carriers.

Regression Models

Rigorous econometric tests for specification error by omitted variables were not possible with available data. However, a deliberate attempt was made to ensure the inclusion of all behaviorally relevant service quality characteristics. European market research studies have revealed that transportation mode selection is influenced by speed, product safety, and certainty of delivery time. Informal market research in Michigan confirmed the interest in these three characteristics. (This informal market research was conducted by the author during August 1973; results are reported by Johnson, pp. 122–24.) The delay in transport equipment delivery and the attention

[1] The dependent variable may alternately be expressed as log $(x_j/x_\bullet)$, where x_j is the quantity of freight services used of mode j and $x_\bullet$ is the total quantity of freight services used from all other modes. For a given observation, a new modal split $(x_j/x_\bullet)'$ resulting from a unit change in level of one service quality variable ($dq_k = 1$) may be obtained by first multiplying the coefficient of regression by the original modal split $(x_j/x_\bullet)$:

$$\frac{d \log(x_j/x_\bullet)}{dq_k} \frac{x_j}{x_\bullet} = \frac{d(x_j/x_\bullet)}{(x_j/x_0)} \frac{x_j}{x_\bullet} = d(x_j/x_\bullet),$$

then adding this resulting change to the original modal split:

$$(x_j/x_0) + d(x_j/x_0) = (x_j/x_\bullet)'.$$

by transportation sales representatives were also revealed to be important characteristics of transportation modes evaluated by Michigan grain shippers.

Two functional forms of the derived demand model were subjected to four specification error tests using sample data from grain elevators.[2] Linear and semilogarithmic (or index) functional forms of the derived demand model and the logit-linear form of the modal selection probability model were evaluated (Johnson). The linear functional form of the derived demand model yields biased error terms, indicating that regression coefficients would also be biased. The index (log-linear) functional form yields unbiased errors by the same tests and thereby unbiased parameter estimates. Heteroskedasticity is not present with either functional form for the sample. Subjection of the logit-linear form of the modal selection probability model to specification error tests suggests that this functional form will provide unbiased estimates without heteroskedasticity.

Data were accumulated from individual Michigan grain elevators using a mail questionnaire survey, distributed as the Michigan Freight Transportation Survey by the Michigan Department of State Highways and Transportation. The instrument measures movement and transport service quality characteristics of outbound grain shipments made by individual firms during the calendar year 1973. Characteristics of movement and service quality were measured for both motor and railroad modes.

The derived demand relationship for outbound grain shipments by railroad bears the log-linear form of

$$(9) \quad x_r = d_r(S, T, R, D, Sp_r, A_r, A_m, V_r, V_m, L_r, L_m, B),$$

where x_r = quantity of rail service demanded (tons), S = an indicator of firm size (1,000 bushel storage units), T = 1 if the firm owns a truck and 0 if not, R = 1 if the firm owns or leases a rail car and 0 if not, D = average distance of rail shipments (miles), Sp_r = average railroad speed (miles per day), A_r = availability of railroad cars (average days of delivery delay), A_m = availability of motor equipment (average days of delivery delay), V_r = number of promotional visits by railroad firms, V_m = number of promotional visits by trucking firms, L_r = average value of damage in rail transit per $1,000 value, L_m = average value of damage in truck transit per $1,000 value, and B = proportion of total shipments intended for railroad but diverted to trucks for lack of railroad cars. Individual regression coefficients are interpreted as proportional changes in the railroad service demanded due to unit changes in movement, firm, and service quality variables. Regression coefficients differ from theoretical results, equations (5) and (6), only in that the log-linear functional form provides proportional rather than absolute measures of response to demand determinants. Partial, own, and cross-service quality elasticities are obtained by multiplying regression coefficients by observed levels of associated service attributes.

The modal selection probability relationship uses the same explanatory variables with $\ln \frac{P_r}{1 - P_r}$ as the dependent variable for which P_r is the proportion of grain shipped by railroad from the individual observed firms during the sample year. When only railroad and motor transport modes are considered, the logit form becomes merely the logarithm of the ratio of rail to motor usage. Individual regression coefficients are interpreted as proportional changes in the ratio of railroad to motor carriage used with unit changes in quality variables. Partial, own, and cross-elasticities of modal selection probability are obtained by multiplying regression coefficients by observed levels of associated service attributes.

Quality of service variables are measured in their own natural units. The implicit price associated with railroad speed is the value of interest charges on inventory in transit. The truck speed counterpart could not be included, for most truck shipments were of less than one day. Implicit consumption costs associated with unexpected delays in railroad and motor equipment delivery are the sums of storage costs and inventory charges for each day products are held waiting for movement equipment. The number of promotional contacts serves to represent the degree of effort by transportation companies to please customers. The implicit values associated with

[2] These tests are RESET, RASET, KOMSET, and BAMSET developed by Ramsey. The first three are a battery of independent tests for biasedness of estimated errors produced by using the functional form being tested. These three tests are based upon regression on principal components, the nonparametric rank order test, and the Kolmogorov-Smirnov statistic, respectively. The BAMSET test indicates whether heteroskedasticity exists with the chosen functional form. This test is based upon Bartlett's M-statistic.

these variables include reduction in management requirements to establish rates and schedules of shipment. Damage and loss in transit is costly in terms of poor customer service, interest losses on money frozen in damage claims, and uninsured losses. Finally, the proportion of total shipments intended for railroad shipment but diverted to motor carriers for lack of railroad cars represents reliability of outbound service. The value of service reliability lies in efficient use of elevator storage facilities. Across firms, shipping patterns are likely to vary by individual firm characteristics of firm size and ownership of transportation equipment.

Regression Results

The index and logit equations are estimated using ordinary least squares regression with data from twenty grain elevator firms.[3] Regression on models incorporating all previously mentioned variables reveals the presence of multicollinearity. To enhance efficiency, estimators are formed with deletions of highly correlated variables. Where parameter estimates do not change substantially and where efficiency measures improve, valid interpretation with abbreviated models is possible.

Regression results for the derived demand relationship for railroad service are shown in the first equation of table 1. Influences of railroad promotional effort, truck damage, and delays in motor freight equipment delivery are removed from analysis due to high correlation among these variables. Variable deletion does not change the magnitudes of individual coefficients substantially. However, the standard error of the estimate was greatly reduced and the explanatory power of the model was enhanced, as related in the *F*-statistic. The quantity of railroad services demanded by grain shippers is significantly influenced by the firm size, the delay in delivery of railroad cars, and the magnitude of damage and loss in transit. An increase (decrease) in elevator size by 10,000 bushels of storage capacity results in

[3] A large portion of these data were used in testing for specification error in the choice of functional form. Independent data samples must be used to verify these results before using coefficients in demand prediction.

Table 1. Regression Results for Railroad Demand and Railroad Selection Probability Estimators

Demand Determinant	Railroad Demand	Railroad Selection Probability
Constant	11.0332	2.1350
	(1.5893)[a]	(0.9127)

$\bar{R}^2$	0.451	0.744
F	$F_{9,10} = 3.163$	$F_{12,7} = 6.626$

[a] Standard errors of coefficients are given in parentheses.

a 1.3% increase (decrease) in the quantity of railroad service demanded annually, *ceteris paribus*. Each day added to the average delay in receiving railroad cars causes grain shippers to demand 5.6% less railroad service annually, holding other influences constant. The isolated effect of an increase in railroad freight damage of $1 per $1,000 of shipment value is a decline of annual rail service usage by 1.25%.[4] Elasticities of railroad demand with respect to firm size and service quality characteristics are shown in table 2 for mean firm size and service quality levels.

Regression results for the modal selection probability model appear in the second equation of table 1. The model including all potentially influential variables appears useful. Variable deletion to enhance estimator efficiency is not possible because highly correlated variables appear to affect modal selection; variable deletion would probably bias remaining estimates.

Three movement and firm characteristics and four service quality characteristics appear to influence proportionate use of transport modes. For an increase (decrease) in the average distance to market of one hundred miles, the proportion of rail to truck shipment increases (decreases) by 29%, *ceteris paribus*. This may be explained as a rapidly declining substitutability of truck for rail service for longer distance distribution patterns.

Firm size and truck ownership affect the proportion of modal services used. Larger firms tend to place proportionally greater reliance upon motor carriage than do smaller grain handlers. As the elevator storage capacity increases by 10,000 bushels, the ratio of rail to truck shipment decreases by 3.7%, *ceteris paribus*. The influence of truck ownership upon the proportionate use of the rail mode is extreme in magnitude but strongly suggests that truck ownership by grain handling firms reduces proportionate use of rail transportation. These results may imply scale economies in truck ownership that allow larger firms to command a truck fleet.

Promotional effort by transportation companies appears to be important in selecting transportation modes. An additional contact by a trucking firm decreases the ratio of rail to motor usage by 6.7%, holding other influences constant. An additional contact by a railroad company will increase the ratio by 55%, *ceteris paribus*. Promotional contacts by railroad firms are few, and there may exist diminishing returns at higher levels of effort. However, at existing low levels of promotional effort, personalizing railroading may have high payoff from grain elevators.

Table 2. Elasticities of Railroad Demand with Respect to Firm Size and Service Quality

Demand Determinant	Mean Level	Elasticity
Firm size (1,000 bu. storage)	294.6	0.38
Rail equipment delay (days)	15.6	−0.88
Damage by railroad ($1/$1,000 shipment value)	14.4	−0.18

Other service quality results are less intuitively appealing. The faster is railroad service or the less reliable is delivery of trucking equipment, the smaller is the relative amount of railroad service used, *ceteris paribus*. The relative preference for slower service may indicate that the value of railroad cars as storage containers for shipments of undetermined destination exceeds the loss in inventory charges on grain owned during transit. Reasons for the inverse relationship between delay in motor equipment delivery and the ratio of rail to motor carriage used are unclear but may be related to multicollinearity. Elasticities of modal selection probability are shown in table 3 for mean levels of movement, firm, and service quality variables.

Conclusions

Statistical experience has been gained by demonstrating procedures for estimating derived demand and modal selection probability functions for grain movements. Regression results reveal that the index form of the derived demand relationship isolates the influence of several important railroad service demand determinants even with small samples of microeconomic data. Delay in railroad car delivery and damage in railroad transit appear to cause significant reductions in total annual volumes of grain shipments by railroad. The degree of demand responsiveness to these service qualities tends to be inelastic.

From the information on modal selection

[4] A strong conclusion cannot be made based upon this latter result. Motor carrier and railroad damage are highly related ($r^2 = 0.882$) in the test sample and the significance of the railroad damage influence depends upon the deletion of the truck damage variable from the model.

Table 3. Elasticities of Modal Selection Probability for Railroad Service[a]

Demand Determinant	Mean Level	Elasticity
Market distance (miles)	679.0	1.97
Storage capacity (1,000 bu. storage)	294.6	−1.09
Truck promotional effort (no.)	4.0	−0.27
Rail promotional effort (no.)	2.8	1.57
Truck equipment delay (days)	1.9	−0.78
Railroad speed (miles/day)	74.0	−2.17

[a] Elasticity of modal split with respect to truck ownership cannot be calculated for truck ownership is indicated by a binary variable.

probability elasticity estimates, it is inferred that the proportionate use of railroad transport to ship grain would be increased more than in proportion to increases in distance to grain markets. Grain elevator firms of larger size place relatively more importance upon motor carriage than do smaller firms. The relative proportion of rail to truck transport demand in the grain industry is highly positively responsive to the promotional effort by railroad firms and slightly negatively related to the promotional effort by trucking firms.

Market research and testimony before Interstate Commerce Commission line abandonment hearings have suggested that service quality has a major impact upon quantity of railroad service demanded and thereby upon line viability. Results of regression on the derived demand model support the notion that service quality does tend to affect railroad service demand but not to the extent previously suggested. The total quantity of railroad services demanded by grain shippers bears inelastic response to important service quality influences.

The difference between vocal complaint and action can be explained by the concept of economic action thresholds. In a transportation market with discontinuous opportunities, a shipper may be inconvenienced by relatively poor service of the railroad mode, while operating costs associated with poor service quality may not exceed the difference between published railroad and motor carrier freight rates. Given a particular firm output level, the less costly transportation mode may decrease service quality until the effective price of consuming services equals the effective price of the next least expensive mode. Only at this level of service deterioration will the shipper have reached an economic action threshold that causes a change in modes. However, aside from traffic diversion, an increase in the effective price of the least costly mode may raise marginal production costs of the shipper firm, discouraging some traffic.

More statistical experience with transportation demand estimation is required to verify estimates of service quality and modal split elasticities before using these parameters in transportation planning. Further studies with new data samples are recommended to derive independent estimates using knowledge of variable selection and functional form developed here as prior information. Also, empirical investigation of transportation demand for the movement of commodities other than grain is needed to expand knowledge of basic transportation market characteristics.

A Model of Consumer Goods Characteristics

George W. Ladd and Veraphol Suvannunt

This paper derives and tests two hypotheses concerning characteristics of purchased consumer goods. One hypothesis states retail price paid is a weighted linear combination of a product's yields of characteristics, each weight being a marginal implicit price of a characteristic. The second hypothesis expresses consumer demand for a product as a function of income, product prices, and product's yields of characteristics. Statistical results are consistent with the hypotheses. One model used in this paper is the consumer goods counterpart to the model used by Ladd and Martin in studying prices and demands for input characteristics.

Key words: hedonic prices, product characteristics, quality.

In a study carried out nearly fifty years ago, Waugh concluded, "There is a distinct tendency for market prices of many commodities to vary with certain physical characteristics which the consumer identifies with quality, and the relation of these characteristics to prices may in many cases be fairly accurately determined by statistical analysis. If this generalization is accepted as true, it opens up a field in the theory of prices which has been practically untouched" (1929, p. 87). This paper deals with this "field in the theory of prices" by developing a model—the consumer goods characteristics model (CGCM)—that yields the two hypotheses that are the themes of this paper. These are: for each product consumed, the price paid by the consumer equals the sum of the marginal monetary values of the product's characteristics; the marginal monetary value of each characteristic equals the quantity of the characteristic obtained from the marginal unit of the product consumed multiplied by the marginal implicit price of the characteristic (theme 1), and consumer demand functions for goods are affected by characteristics of the goods (theme 2).

The CGCM looks upon a product as a collection of characteristics. Product heterogeneity arises because different products contain different kinds, different amounts, or both of various characteristics. CGCM is therefore useful for studying issues involving product heterogeneity such as product differentiation, quality, and grades and standards.

After developing the hypotheses stated in themes 1 and 2, all available statistical evidence is summarized. Then a number of applications are discussed. (Themes 1 and 2 refer to consumer goods. Two similar themes that apply to production inputs are discussed by Ladd and Martin.)

Theoretical Model

Products are wanted because of the utilities they provide. The utilities provided depend upon the product characteristics. Hence, the total amount of utility a consumer enjoys from his purchases of products depends upon the total amounts of product characteristics purchased. Let x_{0j} be the total amount of the jth product characteristic provided to the consumer by consumption of all products. Let x_{ij} be the quantity of the jth characteristic provided by one unit of product i. For example, x_{ij} might measure the length of an automobile, the presence or absence of an automatic transmission, or the amount of preparation time saved by using a TV dinner. Let q_i represent the quantity of the ith product consumed. Suppose we have n products and each of the first m product characteristics is provided by

George W. Ladd is a professor of economics at Iowa State University, Ames, and Veraphol Suvannunt is in the Department of Business Economics in the Ministry of Commerce of Thailand.

Journal Paper No. J-8341 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa, Project No. 1906. This paper is partly a condensation and partly an extension of Suvannunt's thesis. The authors are grateful to the editors and anonymous referees for their helpful comments.

several products, but each product also provides a unique characteristic provided by no other product. Then total consumption of each characteristic can be expressed as a function of quantities of products consumed and of consumption input-output coefficients:

$$(1) \quad x_{0j} = f_j(q_1, q_2, \ldots, q_n, x_{1j}, x_{2j}, \ldots, x_{nj}) \text{ for } j = 1, 2, \ldots, m,$$

and

$$x_{0m+i} = f_{m+i}(q_i, x_{im+i}) \quad \text{for } i = 1, 2, \ldots, n.$$

The consumer's utility function is expressed as

$$(2) \quad U = U(x_{01}, x_{02}, \ldots, x_{0m}, x_{0m+1}, \ldots, x_{0m+n}).$$

Because each x_{0j} is a function of the q_i's and the x_{ij}'s,

$$(3) \quad U = U(q_1, q_2, \ldots, q_n, x_{11}, x_{12}, \ldots, x_{1m}, x_{21}, \ldots, x_{nm}, \ldots, x_{nm+n}).$$

It is assumed that the consumer can vary only the q_i's. The magnitudes of the x_{ij}'s are parameters to the consumer; their magnitudes are determined by producers.

The consumer is assumed to maximize equation (2) subject to the budget constraint

$$(4) \quad \sum_i p_i q_i = I,$$

where p_i is the fixed price paid for the ith product, and I is the consumer's fixed money income, that is, the consumer selects the values of the q_i that maximize the Lagrangian

$$(5) \quad L = U(x_{01}, x_{02}, \ldots, x_{0m+n}) - \lambda(\sum_i p_i q_i - I).$$

The consumer is viewed as selecting the combination of products that provides the combination of total product characteristics that maximizes utility. Choices of products are based on their different characteristics. Because the x_{0j}'s are functions of the q_i's, compound function (function of a function) rules for differentiating U must be used:

$$(6) \quad \partial L/\partial q_i = 0 = \sum_j(\partial U/\partial x_{0j})(\partial x_{0j}/\partial q_i) + (\partial U/\partial x_{0m+i})(\partial x_{0m+i}/\partial q_i) - \lambda p_i.$$

To assure a unique maximum, the Hessian of U is assumed negative definite and the bordered Hessian of L is assumed negative semidefinite.

The marginal utility of income is λ: $\lambda = \partial U/\partial I$. Substituting this expression into equation (6) and solving for p_i yields

$$(7) \quad p_i = \sum_j(\partial x_{0j}/\partial q_i)[(\partial U/\partial x_{0j})/(\partial U/\partial I)] + (\partial x_{0m+i}/\partial q_i)[(\partial U/\partial x_{0m+i})/(\partial U/\partial I)].$$

The marginal yield of the jth product characteristic by the ith product is $\partial x_{0j}/\partial q_i$, e.g., the amount of protein per pound of a particular steak. The marginal yield of the ith product's unique characteristic is $\partial x_{0m+i}/\partial q_i$. In the bracketed terms, $\partial U/\partial x_{0j}$ is the marginal utility of the jth product characteristic, and $\partial U/\partial I$ is the marginal utility of income. Their ratio is the marginal rate of substitution between income and the jth product characteristic. By equation (4), income equals total expenditure. Therefore, the bracketed term can be interpreted as the marginal rate of substitution between expenditure and the jth product characteristic, that is, as the (marginal) implicit or imputed price paid for the jth product characteristic. For convenience, write $(\partial U/\partial x_{0j})/(\partial U/\partial I) = \partial I/\partial x_{0j} = \partial E/\partial x_{0j}$, where E = total expenditure on all products. Assume each unit of each product supplies one unit of its own unique characteristic. Then, $\partial x_{0m+i}/\partial q_i = 1$, and equation (7) becomes

$$(8) \quad p_i = \sum_j(\partial x_{0j}/\partial q_i)(\partial E/\partial x_{0j}) + \partial E/\partial x_{0m+i}.$$

Equation (8) states theme 1.
